which account for 36 out of the 73 lines in the arc spectrum of zinc. The strong line 2138·3 which, according to J. Stark and S. Kinoshita, is the most intense line in the spectrum of zinc at a low temp., is not included in the formulæ; and several other intense lines are also not accounted for. The line-series in the spectrum of zinc have been studied by J. R. Rydberg, W. M. Watts, M. Reinganum, F. Paschen and E. Back, E. Hulthén, A. Kratzer, C. Runge and F. Paschen, A. S. King, L. Janicki, F. A. Saunders, N. A. Kent, P. G. Nutting, A. de Gramont, etc. E. Cappel studied the effect of *temperature* on the sensitiveness of the spectral reactions of zinc. The effect of *pressure* on the spectrum of zinc has been investigated by J. S. Ames and W. J. Humphreys; the *effect of hydrogen* by H. Crew, and R. A. Porter; and the last-named also studied the *effect of nitrogen*; and S. Procopiu various other gases. H. Finger, and B. de la Roche also studied the influence of the gaseous medium on the spectrum of zinc. A. Hagenbach and H. Schumacher studied the line spectrum of zinc in the electrodeless ring discharge tube. J. Formanek states that zinc salts do not give a *dauerndes und brauchbares flame spectrum*. G. D. Liveing and J. Dewar found no spectral lines when detonating gas is exploded in a zinc tube. W. N. Hartley found that the spectrum of zinc in the oxy-hydrogen flame is continuous. The flame spectrum of zinc has been investigated by A. Mitscherlich, A. Gouy, G. D. Liveing and J. Dewar, J. N. Lockyer, H. Ramage, P. Lewis, C. de Wattedville, A. A. Michelson, M. Hamy, L. Janicki, etc. C. Ramsauer and F. Wolf studied the duration of the spectral lines in an extinguished arc. The **ultra-violet spectrum** of zinc has been investigated by G. G. Stokes, W. A. Miller, J. L. Soret, R. A. Sawyer, A. Cornu, G. D. Liveing and J. Dewar, L. Bell, G. Berndt, H. Deslandres, L. and E. Bloch, R. A. Millikan, F. Exner and E. Haschek, J. M. Eder and E. Valenta, E. Néculecé, etc. According to A. de Gramont, the ultra-violet lines 3345·2, 3303·0, and 3384·4 are very sensitive and persist even with very small amounts of zinc. J. J. Dobbie and J. J. Fox found zinc vapour has some faint absorption bands in the ultra-violet. E. Hulthén studied the band spectrum of zinc. The **ultra-red spectrum** has been investigated by F. Paschen, H. Becquerel, etc. The **Zeeman effect** has been investigated by P. Zeeman, A. A. Michelson, T. Preston, H. M. Reese, K. Yamada, C. Runge and F. Paschen, A. Färber, A. Stettenheimer, P. Weiss and A. Cotton, W. A. Miller, H. Lunelund, A. Dufour, etc. F. L. Mohler and co-workers found the **resonance potential** of zinc vapour to be 4·18–5·65 volts, and the **ionization potential** 9·3 volts, and for the latter J. C. McLennan and J. F. T. Young gave 9·4 volts, K. T. Compton gave 3·07–3·74 volts for the minimum ionization potential. M. N. Saha has made observations on this subject. B. E. Moore studied the excitation stages in the arc spectrum of zinc.

According to J. Formanek,¹⁸ soln. of zinc salts are colourless, and they give no **absorption spectrum**; but a neutral soln. of zinc chloride reacts with an alcoholic tincture of alkanna, and produces a reddish-violet soln. which has an absorption spectrum different from the tincture alone. W. N. Hartley found that a 200 cm. column of a soln. of a mol of zinc nitrate in a litre of water shows a complete absorption of rays with a wave-length beyond $\lambda=346$. P. Vaillant studied the absorption spectrum of zinc permanganate; and T. Retschinsky that of fused zinc chloride.

According to L. Weiller,¹⁹ the **electrical conductivity** of zinc is 29·9 when that of silver is 100; G. Wiedemann gave 27·3; A. Matthiessen and A. von Bose, 29·02 at 0°; A. Emo, 26·991; and R. Benoit, 25·9 for the cold hammered metal. If the conductivity of mercury be unity, that of zinc at 0° is 15·88 to 15·99 according to A. Oberbeck and J. Bergmann; 17·52 at 0°, according to A. Matthiessen and A. von Bose; and 16·10, according to R. Benoit. The electrical conductivity in

reciprocal ohms when the value for mercury at 0° is 1.063×10^4 , was given by R. Haas as 17.60×10^4 at 0° ; by A. Sturm, as 18.60×10^4 at 0° ; by A. Oberbeck and J. Bergmann, as 16.93×10^4 ; by W. Jäger and H. Diesselhorst, as 16.51×10^4 at 18° , and 12.59×10^4 at 100° for pure zinc, and 15.83×10^4 at 18° , and 12.13×10^4 for 98.6 per cent. zinc with 0.25 per cent. copper, and 1.1 per cent. lead. L. de la Rive gave for the conductivity of the solid at the m.p., 5.43×10^4 , and of the liquid at the m.p. 2.7×10^4 , and at 440° , 2.69×10^4 . A. Matthiessen and A. von Bose gave for the conductivity at θ° , $1 - 0.0037047\theta + 0.00008274\theta^2$; and C. Benedicks and R. Arpi, between 15° and 300° , $5.45(1 + 0.0039\theta + 0.0000017\theta^2)$ microhms. H. Tsutsumi found a marked decrease in the electrical conductivity of zinc during melting, as illustrated by Fig. 11, where the electrical conductivity is

FIG. 11.—Electrical Conductivity. Curve of Liquid and Solid Zinc.

FIG. 12.—Wiedemann's Ratio of Liquid and Solid Zinc.

expressed in reciprocal ohms per c.c. Wiedmann's ratio, Thermal conductivity \div Electrical conductivity, is well satisfied for solid zinc, but fails completely with the metal in the liquid state.

The **electrical resistance**, R , in ohms per cm. cube, is the reciprocal of the conductivity. J. Dewar and J. A. Fleming found:

	0°	-50°	-77.8°	-100°	-150°	-191.1°	-200°	-252.9°
R_θ	5.75	4.04	3.97	2.90	2.00	1.23	1.39	0.0511
R_θ/R_0	1.00	0.703	0.691	0.504	0.348	0.314	0.242	0.0089

E. F. Northrup and V. A. Suydam found for temp. above atmospheric:

	100°	300°	415°	427°	450°	500° (l)	500° (s)	700°	850°
R	7.95	13.25	17.00	37.30	37.08	36.60	35.90	35.60	35.74
R_θ/R_0	1.38	2.30	2.96	6.49	6.46	6.36	6.25	6.19	6.21

H. le Chatelier found a transformation point in the electrical resistance of zinc between 340° and 350° ; and C. Benedicks found two breaks in the temp.-resistance curve (a) between 160° and 170° , and (b) between 320° and 330° —the latter was identified with H. le Chatelier's point; this was confirmed by K. Monckmeyer and M. Werner. C. Benedicks and R. Arpi also confirmed the existence of the points a and b, and found a third point (c) at about 270° ; they concluded that these points do not belong to pure zinc, but rather to zinc with cadmium as an impurity, and the points a and b mark the solubility limits of the homogeneous zinc-rich solid soln., while the third point c marks the eutectic arrest. This view is not confirmed by K. E. Bingham in her work on the electrical resistance of zinc which has been annealed at different temp. and then quenched. She found a critical point between 200° and 210° , and between 330° and 340° . The temp.-resistance curve of E. F. Northrup does not show these breaks. H. Tomlinson found the resistance of a zinc wire is increased if it is suspended with a load; and Lord Kelvin (W. Thomson), and J. Hopps observed the change in the resistance by twisting the wire; O. Chwolson found the resistance of a zinc wire decreased by annealing. The effect of temperature on the resistance of zinc has been measured by S. Kalischer,

F. Uppenborn, L. de la Rive, and by G. Vicentini with D. Omodei, and with C. Cattaneo. P. W. Bridgman gave 0.00416 for the temp. coeff., W. Jäger and H. Diesselhorst, 0.00412; and L. Holborn, 0.00415. The effect of *pressure* on the electrical resistance of zinc has been measured by E. Lisell, and by P. W. Bridgman. The latter found:

	0°	25°	50°	75°	100°
R	1.0000	1.1017	1.2050	1.3098	1.4159
Press. coeff. at 0 kgrm. . .	-0.0,540	-0.0,533	-0.0,529	-0.0,526	-0.0,524
Press. coeff. at 12,000 kgrms.	-0.0,400	-0.0,394	-0.0,389	-0.0,387	-0.0,385
Average	-0.0,4700	-0.0,4634	-0.0,4590	-0.0,4562	-0.0,4544

E. Lisell gave for the press. coeff. at 0° -0.0,559, against P. W. Bridgman's -0.0,540. O. Jaamaa and Y. E. G. Leinberg measured the resistance of powdered zinc mixed with marble.

The potential difference between zinc and other metals.—When a zinc rod is rubbed with a flannel, A. Macfarlane²⁰ found that it becomes feebly electro-negative. The voltaic series of metals was arranged by A. Volta, T. Seebeck, J. C. E. Pécelet, P. S. Munck af Rosenschöld, C. H. Pfaff, A. Gaugain, etc., and is in general agreement with . . . Al, Zn, Sn, Cd, Pb, Sb, Bi, nickel-brass, brass, Hg, Fe, . . . There are small differences in the position of some members of the series due possibly to the presence of impurities, nature of the surface, etc. The temp. has but little influence on the results. R. Kohlrausch measured the potential difference between zinc and other metals, that is, the **Volta effect** of zinc against different commercial metals, in volts at 18°:

	C	Cu	Fe	Pb	Pt	Sn	Zn amalgam	Brass
Zn	-1.096	-0.750	-0.600	-0.210	-0.281	-0.281	-0.144	-0.679
Zn amalgam	-1.208	-0.894	-0.744	-0.357	-0.125	-0.463	-0.144	-0.822

E. Gerland found for Zn: Cu, 100; Zn: Ag, 180.7; and Zn: Au, 115. Measurements have also been made by W. Hankel, R. B. Clifton, W. E. Ayrton and J. Perry, W. Hallwachs, J. L. Hoorweg, H. Pellet, F. Exner and J. Tuma, W. Thomson, E. Becquerel, J. Brown, and F. Schulze-Berge. The theory has been investigated by H. Greinacher, and E. Warburg and H. Greinacher. According to A. L. Hughes, zinc freed from occluded gases by distillation in vacuo is slightly electronegative to platinum, and it becomes electropositive as air is absorbed by the metal until a maximum value is attained.

A. Coehn and A. Lotz²¹ found that zinc in vacuo is negatively charged against glass. T. Seebeck, W. Hankel, E. H. Hall, etc., have studied the e.m.f. developed by zinc coupled with other metals, and they placed it near copper and silver; A. Heil placed it between nickel and bismuth. E. Wagner found the **thermoelectric force**, or the **Seebeck effect**, of the *zinc-platinum couple* is 0.79 millivolt and the current flows from a junction at 100° to a junction at 0° to the platinum; J. Dewar and J. A. Fleming gave 0.77; W. Jäger and H. Diesselhorst, 0.75; K. Noll, 0.74; and W. H. Steele, 0.60. Lord Kelvin (W. Thomson) found the inversion with the Zn-Pt couple to be 8.2°. J. Dewar and J. A. Fleming gave for the *zinc-lead couple*, with one junction at 0° and the other at θ , in C.G.S. units:

θ	100.2°	70.4°	50.4°	21.4°	7.5°	-3.3°	-80.6°	-204.8°
E.m.f.	+32390	+20920	+14100	+5140	+1620	-810	-17130	-33000

P. G. Tait gave for the Zn-Pb couple $2.32 + 0.0238\theta$ microvolts, or 2.79 microvolts at 20° and 3.51 at 50°. The neutral point is -98°. A. Matthiessen gave 3.7 microvolts for the thermoelectric power of the Pb-Zn couple; and K. Noll, 3.318 microvolts at 50°. P. W. Bridgman represented the Seebeck effect, E , with lead at atm. press. $E = (3.047\theta - 0.00495\theta^2) \times 10^{-6}$ volts. C. G. Knott studied the e.m.f. of the *zinc-iron couple*, and A. Palme found that the current attains a maximum of about one millivolt between 200° and 250°. Lord Kelvin found the current with a *zinc-gold couple* increases 0.20×10^{-6} volts per degree between 16° and 50°. No

breaks were found in the thermal e.m.f. and temp. curve of a zinc and iron couple by K. E. Bingham. E. Becquerel studied the *zinc-copper couple*. K. E. Bingham observed no breaks in the thermal e.m.f. of this couple, although P. N. Lashtchenko, S. F. Bykoff, and S. V. Efremoff obtained a critical value at 310° in the copper-zinc couple. A. Matthiessen studied the *zinc-silver couple*; K. Noll, *zinc-mercury couple*; and A. Heil, the *zinc-cupronickel couple*. P. W. Bridgman gave for the thermoelectric force, E volts $\times 10^6$, for a couple composed of uncompressed zinc, and zinc compressed to a press. p kgrms. per sq. cm., with the junctions at 0°:

			10°	20°	40°	60°	80°	100°
p	2,000	.	+1.1	+2.3	+4.8	+7.8	+10.8	+14.1
	6,000	.	3.6	7.3	15.3	24.0	33.3	43.0
	12,000	.	7.1	14.4	30.1	47.4	66.4	87.4

H. Jahn found for the **Peltier effect**—*vide* magnesium—with zinc against copper —0.68 millivolt, and E. P. le Roux, —0.45 millivolt. H. Jahn gave for the coeff. of the Peltier effect in calories per ampere-hour, —0.58 millivolt; E. P. le Roux, —0.39 millivolt; and E. Edlund, —0.01 millivolt. For the Peltier effect, P , of zinc against lead at atm. press., P. W. Bridgman gave $P = (3.047 - 0.0099\theta)(\theta + 273) \times 10^{-6}$ volts; and for compressed and uncompressed zinc, the Peltier effect in joules per coulomb $\times 10^{-6}$, is:

			0°	20°	40°	60°	80°	100°
p	2,000	.	+30	+35	+41	+48	+50	+63
	6,000	.	98	110	131	150	169	190
	12,000	.	190	218	257	300	351	412

He also gave for the **Thomson effect**, σ , of zinc with lead at atm. press., $\sigma = 0.0099(\theta + 273) \times 10^{-6}$ volts per degree; and for the excess in compressed over uncompressed zinc, in joules per coulomb per degree $\times 10^8$:

			0°	20°	40°	60°	80°	100°
p	2,000	.	+17	+18	+19	+20	+21	+22
	6,000	.	41	44	47	50	53	56
	12,000	.	63	89	118	148	183	220

E. Wagner made some observations on this subject up to 300 kgrms. per sq. cm. press. The **Hall effect** with zinc is $R = +0.00082$. F. Unwin measured the effect of varying the strength of the magnetic field and of temp. on the Hall effect, and other thermo-magnetic phenomena. G. Borelius and F. Gunneson measured the Thomson effect in microvolts per degree, and found 5.9 at 380° K., 2.6 at 300° K., 1.25 at 200° K., 1.1 at 150° K., and 0.8 at 100° K. A. E. Caswell found for the coeff. of the Hall effect, 15.33×10^{-13} at -24.7° ; 8.20×10^{-13} at 25.5° ; 8.38×10^{-13} at 32.6° ; 8.18×10^{-13} at 39.9° ; 8.23×10^{-13} at 41.2° ; and 8.23×10^{-13} at 76.7° . The coeff. of the **Ettingshausen effect** at 17.1° is 0; at 45.2° , 1.76×10^{-8} ; at 60.7° , 2.27×10^{-8} ; and at 76.7° , 3.02×10^{-8} . The coeff. of the **Nernst effect** at -16.2° is 290×10^{-12} ; and at 37.2° , -6.25×10^{-12} . The coeff. of the **Leduc effect** is 37.59×10^{-7} at -16.2° , and 4×10^{-7} at 37.2° .

The potential difference between zinc and electrolytes.—According to R. B. Clifton,²² a clear zinc plate is as strongly electropositive as copper towards water; if the metal is oxidized, it is negative towards water. N. R. Dhar gave 0.41 volt. W. Hankel also noted that the potential difference between zinc and water decreases as the metal is oxidized, and then increases. The action was also studied by W. F. Hillebrand and T. H. Norton. G. T. Fechner gave the series: Zn, Pb, Sn, Fe, Sb, Bi, Cu, Ag, Au. W. Ostwald found zinc to be electronegative towards the *haloid acids*, and *nitric, sulphuric, phosphoric, formic, acetic, propionic, oxalic, and benzoyl sulphuric acids*. J. C. von Yelin studied the action with *nitric, sulphuric hydrochloric, phosphoric, acetic, and tartaric acids*; H. Davy, J. C. Poggen-dorff, M. Faraday, S. Marianini, and G. Wetzlar, *sulphuric acids*; H. C. Oersted, *sulphuric and nitric acid*; H. E. Patten and W. R. Mott, the potential difference with *nitric, sulphuric, hydrochloric, and hydriodic acids*; A. A. de la Rive, and

M. H. Jacobi, nitric acid; J. C. Poggendorff, *hydrosulphuric acid*; M. Berthelot, *boric acid*; H. Davy, J. C. Poggendorff, and J. C. von Yelin studied the potential difference with aq. soln. of *potassium, sodium, and ammonium hydroxides*; F. Kunschert, M. Berthelot, and H. E. Patten and W. R. Mott with *potassium hydroxide*. G. T. Fechner, S. Marianini, J. C. Poggendorff, and J. C. von Yelin studied the potential difference with aq. soln. of *sodium and ammonium chlorides*; H. E. Patten and W. R. Mott, with aq. soln. of *potassium fluoride, potassium chloride* and *sodium chloride*, and *potassium bromide, and iodide*; L. Kahlenberg with aq. pyridine, and aniline soln. of *lithium chloride*; A. de la Rive, *calcium chloride*; E. Bouty, B. Neumann, G. Carrara and L. d'Agostini, J. Moser, with aq. soln. of *zinc chloride*; R. Salvadori studied *ethyl and methyl alcohol* soln. of *potassium chloride*; and G. Carrara and L. d'Agostini, *methyl alcohol* soln. of *zinc chloride*. C. M. van Deventer and H. van Lummel also compared the potential difference of zinc with salts in aq. and in alcoholic soln. R. Suchy studied the potential difference of zinc towards molten zinc chloride. J. C. Poggendorff studied the potential difference with aq. soln. of *sodium sulphate*; H. E. Patten and W. R. Mott, with aq. soln. of *potassium, ferrous, magnesium, cupric, cadmium, and zinc sulphates*; the effect with the last-named salt was also studied by G. de Villemontée, B. Neumann, F. Streintz and O. Strohschneider, W. Ostwald, J. Miesler, N. T. M. Wilsmore, F. Kunschert, F. Paschen, H. Pellat, H. J. S. Sand, A. C. Becquerel, L. Bleekrode, E. Kittler, J. Moser, J. von Hepperger, J. W. Müller, A. Eccher, H. F. Weber, S. Pagliani, M. Chanoz, M. Berthelot, and E. Bouty. M. Berthelot worked with aq. soln. of *cupric sulphate*. J. C. Poggendorff, M. Chanoz, and M. Berthelot studied the potential difference of zinc with an aq. soln. of *potassium sulphide*. The effect of *potassium nitrate* was studied by H. E. Patten and W. R. Mott, and with *zinc nitrate* by A. C. Becquerel, and E. Bouty and B. Neumann. The former also worked with soln. of *potassium phosphate*; P. S. Munck af Rosenschöld, E. Bouty, and H. E. Patten and W. R. Mott, with *potassium carbonate*; B. Neumann, L. Bleekrode, and J. Moser, with *zinc acetate*; H. E. Patten and W. R. Mott, with *potassium tartrate, chromate, and manganate*; *sodium silicate, and tungstate*; *potassium cyanate and thiocyanate*; and with *potassium cyanide*. M. H. Jacobi, L. Bleekrode, F. Spitzer, S. P. Thompson, and S. B. Christy also studied the effect with the last-named salt. M. Berthelot studied the effect of numerous other combinations. In illustration of the variable nature of the electrochemical series in the presence of different soln., M. Faraday gave:

H ₂ SO ₄	Zn, Cd, Sn, Pb, Fe, Ni, Bi, Sb, Cu, Ag
HNO ₃ (dil.) . . .	Zn, Cd, Pb, Sn, Fe, Ni, Bi, Sb, Cu, Ag
HNO ₃ (conc.) . .	Cd, Zn, Pb, Sn, Fe, Bi, Cu, Sb, Ag, Ni
HCl	Zn, Cd, Sn, Pb, Fe, Cu, Bi, Ni, Ag, Sb
KOH	Zn, Sn, Cd, Sb, Pb, Bi, Fe, Cu, Ni, Ag
KSH	Cd, Zn, Cu, Sn, Sb, Ag, Pb, Bi, Ni, Fe

G. Magnanini found the difference in potential in hundredths of a volt between zinc in a normal soln. of sulphuric acid and zinc in the following soln. containing n mols per litre: n -NaOH, -32.1 centivolts; n -KOH, -42.5; $\frac{1}{2}n$ -Na₂SO₄, 1.4; n -Na₂S₂O₃, -5.9; n -KNO₃, 11.8 (variable); n -NaNO₃, 11.5; $\frac{1}{2}n$ -K₂CrO₄, 23.9 (variable); $\frac{1}{2}n$ -K₂Cr₂O₇, 72.8; $\frac{1}{2}n$ -K₂SO₄, 1.8; $\frac{1}{2}n$ -(NH₄)₂SO₄, -0.5; $\frac{1}{2}n$ -K₄FeCy₆, -6.1; 0.167*n*-K₃FeCy₆, 41.0; n -KCys, -1.2; $\frac{1}{2}n$ -Sr(NO₃)₂, 14.8; $\frac{1}{2}n$ -Ba(NO₃)₂, 21.9; n -KClO₃, 10.15; 0.167*n*-KBrO₃; n -NH₄Cl, 2.9; n -KF, 2.8; n -KBr, 2.3; $\frac{1}{2}n$ -Na₂SO₃, 18.4; a soln. of bromine in NaOH, 18.4; n -tartaric acid, 5.5; $\frac{1}{2}n$ -tartaric acid, 4.1; $\frac{1}{2}n$ -potassium sodium tartrate, -7.9 centivolts. The sign of the difference of potential is such that the current flows from the more positive to the less positive metal through the external circuit. T. W. Richards and T. Dunham, and A. Smits measured the potential of zinc in various salt soln.

The potential difference of zinc against other metals in solutions of electrolytes.—Zinc is electropositive to most of the metals, but its character changes more or less when in the presence of electrolytes. On account of the high electropositive character of zinc, and its comparative cheapness, it is extensively employed as one element in galvanic batteries. H. Davy,²³ and J. C. Poggendorff found that zinc becomes more electropositive on amalgamation; and G. Lippmann found that

amalgamated zinc is electropositive towards ordinary zinc in a soln. of zinc sulphate, but there is no difference of potential against purified zinc when the soln. is neutralized with, say, barium carbonate. E. Cohen, and F. Fischer have measured the potential difference of purified zinc against zinc amalgam (90 per cent. mercury), and found 0.000488 volt at 0°, and 0.000750 volt at 25°. The difference of potential of zinc in contact with other metals in sulphuric acid soln. has been studied by J. C. Poggendorff, M. Faraday, H. Davy, G. T. Fechner, C. Wheatstone, R. B. Clifton, C. Hockin and H. A. Taylor, E. Kittler, B. G. Damien, and W. Wolff. The metals tried were tin, copper, silver, cadmium, iron, gold, or platinum against zinc or amalgamated zinc. H. C. Oersted found zinc in fuming sulphuric acid is first positive against lead, then negative, and finally positive. S. Marianini also tried sea-water acidified with sulphuric acid; E. Bouty, W. Wolff, C. Hockin and H. A. Taylor, and B. G. Damien tried zinc against carbon, lead, iron, cadmium brass, tin, copper, silver, gold, and platinum in aq. soln. of zinc sulphate. G. Tammann and W. Wiederholt measured against cadmium in zinc sulphate soln. K. E. Bingham found critical points at about 180° and 310° in the electrolytic potential curve of zinc against other metals in a 10 per cent. soln. of zinc sulphate. The zinc was annealed at different temp. and then quenched. B. G. Damien measured the electrolytic

FIG. 13.—Electrolytic Potential Curve of Zinc Annealed at Different Temperatures.

potential of zinc against copper in aq. soln. of potassium, sodium, magnesium, or aluminium sulphate. M. Faraday, C. Wheatstone, and J. C. Poggendorff tried zinc against copper and platinum in dil. hydrochloric acid. N. R. Dhar, G. T. Fechner, J. C. Poggendorff, and B. C. Damien investigated iron, copper, silver, and platinum against zinc or amalgamated zinc in soln. of sodium, potassium, ammonium, barium, strontium, or zinc chloride. J. C. Poggendorff, and B. G. Damien studied zinc against copper, iron, silver, and platinum in aq. soln. of potassium bromide; and of zinc against bismuth, tin, iron, copper, silver, and platinum in aq. soln. of potassium iodide. A. P. Laurie studied the potential of zinc against platinum in aq. soln. of zinc iodide, containing iodine. H. Davy, M. Faraday, A. A. de la Rive, A. Avogadro and V. Michelotti, and J. C. Poggendorff measured the potential difference of amalgamated zinc against copper and platinum in dil. nitric acid; B. G. Damien, zinc against copper in soln. of potassium, sodium, ammonium, barium, or strontium nitrate; W. Wolff, likewise, in soln. of zinc nitrate; and H. C. Oersted, of zinc against tin in soln. of silver nitrate. H. Davy, M. Faraday, B. G. Damien, and J. C. Poggendorff measured the difference of potential of zinc against antimony, iron, silver, and platinum in soln. of potassium hydroxide. P. S. Munck af Rosenschöld, J. C. Poggendorff, and B. G. Damien investigated the difference of potential of zinc against copper, tin, iron, and platinum in aq. soln. of potassium and sodium carbonates. J. C. Poggendorff, W. Skey, S. P. Thompson, and F. Kunschert found the potential difference of zinc against bismuth, iron, copper, silver, and carbon in aq. soln. of potassium cyanide; J. C. Poggendorff also worked with a soln. of potassium ferrocyanide. A. Naccari and M. Bellati studied zinc or amalgamated zinc against carbon in aq. soln. of chromic acid. E. Branly studied the difference of potential between zinc and copper in glycerol; A. Righi, in petroleum J. L. Hoorweg, in stearic acid, paraffin, spermaceti, rape seed oil, shellac, wax, and sulphur; and C. M. van Deventer and H. van Lummel, in ethyl alcohol and propyl alcohol. J. J. van Laar showed that the normal current between magnesium and zinc in aq. soln. can be reversed in alcoholic soln.

M. H. Jacobi found zinc in nitric acid is electronegative against zinc, cadmium, tin, copper, or silver in a soln. of potassium cyanide; and electropositive against nickel, antimony, lead, mercury, bismuth, iron, platinum, or carbon in a soln. of potassium cyanide. J. C. Poggendorff studied the potential difference of zinc

or amalgamated zinc in dil. sulphuric acid against copper in a soln. of cupric sulphate, or platinum in nitric acid, or carbon in nitric or chromic acid. H. Buff studied the potential difference of zinc in a soln. of sulphuric acid against carbon, pyrolusite, pyrites, or cast iron in nitric acid; he also studied zinc in a soln. of sodium chloride against platinum, copper, or zinc in a soln. of potassium polysulphide. J. P. Joule studied zinc in aq. potassium hydroxide against iron, coke, gold, or platinum in nitric acid, or copper in a soln. of cupric sulphate. J. Regnault studied zinc in a soln. of iodine in potassium iodide against carbon in a soln. of potassium iodide containing iodine, bromine, or chlorine; F. M. Raoult, $\text{Zn} : \text{ZnSO}_4, \text{Pb}(\text{C}_2\text{H}_3\text{O}_2)_2$; Pb. F. Streintz measured the potential difference of zinc in soln. of the nitrates against magnesium, aluminium, bismuth, cadmium, tin, lead, iron, nickel, cobalt, copper, and silver; likewise also of zinc in soln. of the sulphates, or of the chlorides against these same metals. E. F. Herroun studied $\text{Zn} : \text{ZnSO}_4, \text{SnSO}_4 : \text{Sn}$; and also $\text{Zn} : \text{H}_2\text{SO}_4, \text{SnSO}_4 : \text{Sn}$; he also studied combinations with the two metals in soln. of the respective chlorides or iodides; and of $\text{Zn} : \text{ZnCl}_2, \text{Na}_2\text{PtCl}_6 : \text{Pt}$, or of $\text{Zn} : \text{ZnCl}_2, \text{AuCl}_3 : \text{Au}$. Various other combinations have been studied by G. Magnanini, G. J. R. Blochmann, C. L. Speyers, C. R. A. Wright and C. Thompson, W. Beetz, and M. Berthelot. Latimer Clark's combination $\text{Zn} : \text{ZnSO}_4, \text{Hg}_2\text{SO}_4 : \text{Hg}$, with a sat. soln. of zinc sulphate has an e.m.f. at θ° of $1.4328 - 0.00119(\theta - 15) - 0.000007(\theta - 15)^2$ volt, and its use as a normal element has been discussed by W. Jäger, and H. Kahle. J. F. Daniell's cell $\text{Zn} : \text{ZnSO}_4, \text{CuSO}_4 : \text{Cu}$ has been discussed by J. C. Poggendorff, F. Fuchs, A. F. Svanberg, E. Branly, C. R. A. Wright, C. Fromme, E. Kittler, S. Carhart, C. Cattaneo, H. Pellat, F. M. Raoult, G. Meyer, W. H. Preece, F. Petruschewsky, etc.—*vide* 1. 16, 3.

According to R. Suchy, Daniell's cell with molten salts instead of aq. soln. gives analogous results. Other combinations with molten salts have been investigated by O. H. Weber, R. Lorenz, etc.—*e.g.* V. Buscemi, W. Reinders, L. Poincaré, and J. Brown studied $\text{Zn} : \text{ZnCl}_2, \text{SnCl}_2 : \text{Sn}$; V. Czepinsky, $\text{Zn} : \text{ZnBr}_2, \text{PbBr}_2 : \text{Pb}$; R. Suchy, $\text{Zn} : \text{ZnCl}_2, \text{AgCl} : \text{Ag}$; V. Buscemi, $\text{Zn} : \text{ZnCl}_2, \text{HgCl}_2 : \text{Hg}$; W. Reinders, $\text{Zn} : \text{ZnCl}_2, \text{PbCl}_2 : \text{Pb}$; and J. Brown, $\text{Zn} : \text{ZnCl}_2, \text{MgCl}_2 : \text{Mg}$. E. Bouty found the temp. coeff. of the e.m.f. of zinc in fused zinc chloride.

T. W. Richards and G. S. Forbes, F. J. Mellenkamp, etc., have measured the potential of amalgamated zinc electrodes; W. C. Moore measured the potential of the **zinc electrode** in the combination $\text{Zn} | \text{ZnSO}_4$ with the normal calomel electrode, at $20.1^\circ - 25.5^\circ$. For 0.5, 0.1, 0.01, and 0.002*N*- ZnSO_4 the observed electrode potentials are respectively -0.769, -0.790, -0.820, -0.838 volt. The values calculated from $E = 0.0292 \log (C_1/C_2)$ are respectively -0.780, -0.800, -0.829, and -0.850 volt. As W. A. Kistiakowsky has shown, it is necessary to exclude oxygen as completely as possible when setting up the zinc electrode. W. G. Horsch also measured the potential of the zinc electrode in the combination $\text{Zn} | \text{ZnCl}_2, \text{AgCl} | \text{Ag}$. E. Cohen and co-workers measured the effect of *pressure* and *temperature* on the e.m.f. of the zinc electrode; H. Gilbault, and H. Wild, the effect of press.

The **heat of ionization** of zinc per valence is given by W. Ostwald²⁴ as 16,600 cal. The **transport numbers** of zinc ions have been measured by K. Drucker, F. Kohlrausch, W. Hittorf, G. Kümmel, S. Arrhenius, O. Grotrian, J. F. Daniell and W. A. Miller, J. C. d'Almeida, A. Chassy, etc. The **velocities of the ions**, *V*, expressed in mm. per sec., for a potential difference of one volt per mm., were determined by C. L. Weber for soln. containing *n* mols of zinc nitrate per litre :

<i>n</i>	.	.	.	0.2	0.1	0.04	0.02	0.01	0.005	0.0025	0.00125
<i>V</i>	.	.	.	0.091	0.111	0.095	0.077	0.084	0.051	0.052	0.051

W. P. Davey gave 0.76 Å. for the **atomic radius** of the zinc ion in zinc oxide. J. E. Murray and B. Renault investigated the **electrochemical equivalent**; the former found 0.0003287 grm. of zinc to be deposited per ampere-second.

The **decomposition voltages** of aq. soln. of many zinc salts—zinc sulphate,

bromide, phosphate, acetate, oxalate, tartrate, cyanide, and complex salts—have been determined by W. A. Kistiakowsky,²⁵ M. le Blanc, A. Gockel, W. Gaus, F. Kunschert, H. Jahn, J. E. Root, H. E. Patten and W. R. Mott, E. F. Smith and F. Mahr, etc. H. E. Patten measured the decomposition voltage of zinc chloride in acetone soln.; R. Lorenz, and C. C. Garrard the decomposition voltage of molten zinc chloride and bromide. P. A. Favre, H. Jahn, and R. Colley investigated the relation between the thermal and electrical energy required for the decomposition of zinc salts. The electrolytic **solution pressure** of zinc in aq. salt soln. has been investigated by C. R. A. Wright and C. Thompson,²⁶ F. Braun, W. Ostwald, B. Neumann, M. le Blanc, R. A. Lehfeldt, F. Krüger, R. Abegg, C. M. van Deventer and H. van Lummel, etc.; and in alcoholic soln. by H. C. Jones and W. A. Smith, G. Carrara and L. d'Agostini, O. Sackur, etc. The constant works out approximately 10^{11} atm. for aq. soln., and 1.9×10^{10} in ethyl alcohol soln.

The **overvoltage** of hydrogen on zinc electrodes in $N\text{-H}_2\text{SO}_4$ is approximately 0.70 volt. The subject has been investigated by W. A. Caspari,²⁷ F. Kunschert, J. Tafel, E. Müller, A. Coehn and Y. Osaka, etc. The **polarization** of zinc electrodes has been investigated by R. Thöldte,²⁸ J. P. Joule, E. Patry, C. Matteucci, J. Regnaud, A. Oberbeck, K. R. Koch and A. Wüllner, W. J. Müller, T. W. Richards and T. Dunham, H. Buff, J. W. Langley, E. Edlund, F. Neumann, M. le Blanc, E. du Bois-Reymond, M. Corsepilus, J. C. Poggendorff, etc. According to E. Beetz,²⁹ zinc does not become passive by the formation of a superficial film of oxide, because the oxide is electropositive towards copper and silver. W. J. Müller observed an abnormally high polarization in soln. containing OH' -ions, and this is regarded as evidence of the **passivity of zinc**. According to O. Sackur, and M. le Blanc and M. G. Levi, zinc becomes passive in complex soln. of cupric cyanide, or thiocyanate, in soln. of cadmium or nickel nitrate, or ferrous sulphate. W. R. Dunstan and J. R. Hill found that zinc is rendered passive towards soln. of copper sulphate, and towards aerial oxidation by immersion in a one per cent. soln. of potassium dichromate or chromate, or a 0.01–0.1 per cent. soln. of chromic acid. Two per cent. soln. of sodium carbonate or of borax also made zinc partly passive. The passivity is due to a surface film which can be removed by scratching. Washing with alcohol and drying also removes much of the passivity. A. Löb refers the alternating current passivity of zinc to the overvoltage of the hydrogen. A. Thiel attributed the inactivity of zinc to the formation of a black film of undissolved cadmium on the surface. M. Centnerszwer assumed that the period of induction observed when zinc dissolves in dil. acids is due to the passage of zinc from a passive to an active state. He found zinc becomes passive when heated in vacuo or in hydrogen. Since the metal thus treated is less active when rubbed with emery powder, than the untreated metal, he assumed that the passive condition extends below the surface. Active zinc becomes passive by anodic polarization in 2*N*-sulphuric acid, and passive zinc becomes active by cathodic polarization—*vide* the potential of air-free zinc. U. Sborgi and P. Marchetti have studied the anodic behaviour of zinc in sat. soln. of lithium chloride in acetone. A. Günther-Schulze,³⁰ and W. Holtz have investigated the **electrolytic valve action** of zinc in aq. soln. of salts.

The **electric discharge** between zinc poles has been studied by C. E. Guye and A. Bron,³¹ H. T. Barnes and A. N. Shaw, A. Pospeloff, F. Müller, and F. Ehrenhaft. M. Faraday, and E. Becquerel found zinc to be diamagnetic. The disintegration of zinc cathodes has been studied by B. Walter, and F. Braun. For the disintegration under liquids *vide* colloidal zinc. V. L. Chrisler studied the potential gradient of an arc with zinc electrodes; and A. Hörnli, the arc from zinc electrodes.

J. Königsberger found the **magnetic susceptibility** of zinc is -0.70×10^{-6} to -0.94×10^{-6} units of vol.; L. Lombardi found -1.0×10^{-6} units of vol. C. Chéneveau found -0.10×10^{-6} units of mass, and K. Honda found -0.15×10^{-6} units of mass at 18°, and -0.10×10^{-6} at 650°. T. Ishiwara found that the diamagnetic susceptibility of zinc shows a sudden decrease of about 4 per cent. at the m.p. and there is a linear decrease above and below this point.

§ 5. The Physical Properties of Cadmium

Cadmium has a silver-white colour with a bluish-tinge, and a bright lustre, which soon dulls on exposure to air. According to A. Colson, a thin film of cadmium is bluish-violet in transmitted light. The vapour of cadmium is orange-yellow or yellowish-brown, and, according to F. Stromeyer, it produces no distinctive odour. H. Kämmerer¹ obtained silver-white crystals of cadmium, 6–8 mm. long, by distilling the metal in a stream of hydrogen in a combustion tube—the crystals occur as regular octahedrons, dodecahedrons, etc. F. Mylius and R. Funk obtained needle-like crystals and six-sided plates by sublimation of the metal in vacuo.

H. N. Morse and H. C. Jones, H. le Chatelier, E. de Souza, and G. W. A. Kahlbaum also obtained hexagonal crystals by sublimation and the crystals resembled those of zinc and magnesium. G. Rose and H. Kämmerer supposed the crystals to belong to the cubic system, but G. H. Williams, and P. Termier showed that the crystals are bipyramidal and belong to the hexagonal system; the axial ratio is given as $a:c=1:1.335$. G. d'Achiardi, and F. Rinne also made observations on the crystals. As indicated in connection with zinc, this metal and cadmium are isomorphous. According to W. Orloff, the metals beryllium, magnesium, zinc, and cadmium, and also a large number of their compounds, form an eutropic series, and the increase in at. wt. is generally associated with an increase in sp. gr., mol. vol., index of refraction, and mol. refraction, but a decrease in hardness and sp. ht. The c -axis also changes with increasing mol. wt.:

	Be	Mg	Zn	Cd
At. wt.	9.1	24.32	65.37	112.40
$a:c$	1:1.5802	1:1.6242	1:1.3564	1:1.3350

A. W. Hull found the **X-radiograms** of cadmium corresponded with a close-packed hexagonal lattice; they do not fit the hexagonal lattice with an axial ratio 1.335, but require an axial ratio 1.89. The side of the elementary triangular prism is 2.960 Å., and the distance between the nearest atoms in the basal plane is 2.960 Å., and in the pyramid plane, 3.280 Å. The density obtained by dividing the mass of the atoms in an elementary cell, by the vol. of the cell, is 8.74, the observed value is 8.642. L. Hamburger made an ultra-microscopic examination of thin films of cadmium. S. Nishikawa and G. Asahara found that cadmium gives an abrupt change in the pattern of the X-radiogram at about 227°, and they studied the effect of rolling and annealing on the X-radiogram. W. L. Bragg calculated 1.60 Å. for the atomic diameter and M. N. Saha 0.81 Å. for the at. radius.

The cast metal is crystalline; and when sections are polished and etched with dil. nitric acid, or a soln. of cupric sulphate, or sulphuric acid with a few drops of nitric acid, the polygonal crystals are revealed. G. Cartaud found these crystals have the appearance of a mass of cells when a thin layer of cadmium is cast on a glass plate whereby the metal is suddenly cooled. According to H. Behrens, and W. Campbell, dendritic crystals appear on the surfaces of ingots when the crystals grow at the surface, and as the metal solidifies, the liquid part contracts, and sinks, leaving the dendrites standing in relief. The dendrites have the appearance of six-rayed stars, symmetrically arranged about a hexagonal axis, Fig. 14, and "from each axis, there grows a series of parallel branches making an angle of 60° with that axis, and therefore parallel to the next adjacent axis; between each pair of axes another axis begins thus adding to the hexagonal symmetry." M. Volmer, and M. Cook have studied the growth of crystals of cadmium; and G. Tammann and Q. A. Mansuri, the speed of crystallization of compressed powders at different temp., and in different atm.

G. T. Beilby showed that the surface of a crystalline metal which has been produced by breaking, tearing, or filing, by rolling, drawing, hammering, or polishing, is really covered with an amorphous glass-like film, which may be made to crystallize by mechanical treatment, or removed by suitable etching liquids. Zinc loses its crystalline structure when rolled or hammered into foil, or drawn into wire, but, according to S. Kalischer, the crystalline structure of cadmium is not altogether lost by this treatment, and it is made more manifest by heating the metal between 200° and 250°, and etching as indicated above. By annealing the metal over 180°, W. Campbell obtained large polygonal crystals. J. A. Ewing and

FIG. 14.—Dendrites of Cadmium ($\times 33$).

W. Rosenhain annealed the metal at 200°. Z. Jeffries and R. S. Archer said that the lowest temp. at which the recrystallization of cold-worked cadmium has been observed is the room temp. J. N. Greenwood found the spontaneous annealing and recrystallization of chilled cast cadmium occurs at ordinary temp. The slower the cooling of the cast metal the larger the crystals. When cadmium is bent, it emits a crackling noise like tin. J. A. Ewing and W. Rosenhain found that after bending, the crystals show the slip-band structure previously described, and five such slip-bands can be seen in the bottom crystal, Fig. 15. According to F. Mylius and R. Funk, a cast plate of impure cadmium is not homogeneous, for the impurities may collect in separate aggregates. G. Tammann studied the etching of cadmium by a soln. of ammonium nitrate, and by hydrochloric acid.

FIG. 15.—Cadmium Crystals showing Slip-bands.

The **specific gravity** of cadmium was given by J. G. Children² as 8·670; by J. F. John, 8·75; by W. Herapath as 8·650; by C. J. B. Karsten as 8·6355; by A. Baudrimont as 8·6689; by H. Kopp, 8·63; by H. Kämmerer, 8·52 to 8·69; and by H. G. F. Schröder between 8·540 and 8·667. A. Matthiessen gave 8·655 at 11°; G. Quincke, 8·627 at 0°; and G. Vicentini and D. Omodei, 8·6681 at 0°; W. Jäger and H. Diesselhorst, 8·63 at 18°. The best representative value is 8·642. According to F. Stromeyer, the cast metal has a sp. gr. 8·6040, and the hammered metal, 8·6944. J. G. Children, and H. G. F. Schröder also found the sp. gr. of the metal was increased by hammering, but F. C. A. H. Lantsberry found that the sp. gr. of annealed cadmium is 8·6437, and of the cold-worked metal, 8·6379; and J. Johnston and L. H. Adams gave 8·6397 for the sp. gr. of cadmium wire, and 8·6434 for the same after annealing. W. Spring found the sp. gr. of the metal at 17° is 8·642, and after it had been compressed at 20,000 atm., 8·667 at 16°, and no change occurred after a repetition of the treatment; G. W. A. Kahlbaum, K. Roth and P. Seidler also found the sp. gr. of distilled cadmium at 20°/4°, to be 8·6434, and after press., 8·64766; and when annealed at 270°, the sp. gr. was 8·6434, while a cold-drawn wire was found by G. W. A. Kahlbaum and E. Sturm to have a sp. gr. 8·6379. T. M. Lowry and R. G. Parker noted that the sp. gr. of the metal *en masse*, 8·6445, is greater than in the form of filings. This is in accord with the general behaviour of metals. The filings can be regarded as worked or hardened metal. When completely annealed, the metal contracts, but when partially annealed at say 100° or 108°, there is an expansion. T. A. Readwin noted the spontaneous change (expansion) of a coil of rolled cadmium; G. Quincke found the sp. gr. of the fused metal to be 8·394; H. Siedentopf, 7·9252; M. Töpler, 7·975; and T. R. Hogness gave $D=8·02-0·00110(\theta-320)$ for the sp. gr. of molten cadmium at θ° . G. Vicentini and D. Omodei found the sp. gr. of the solid metal at 318° is 8·3665, and of the liquid metal at 318°, 7·987; there is therefore a contraction on solidification as was also observed by F. Nies and A. Winkelmann. R. Arpi gave

Sp. gr.	349°	406°	466°	506°	550°	603°
	7·94	7·88	7·82	7·78	7·74	7·69

from which the coeff. of expansion of the liquid can be computed. W. Broniewsky found the vol. changed 0·0472 part on melting. T. M. Lowry found the sp. gr. of cadmium is decreased by annealing at 100°. H. Ramage compared the sp. gr. of the metals beryllium, magnesium, zinc, cadmium, and mercury.

According to E. Cohen and W. D. Helderman,³ when cadmium is heated for a considerable time in contact with a soln. of cadmium sulphate at 70° and 100°, its density decreases from 8·643 to 8·633 at 25°/4°, and the change is supposed to be due to an enantiotropic transformation which occurs at 64·9; and this is

supposed to account for the disintegration of cadmium wires heated to 80° , reported by A. Matthiessen and A. von Bose. The transition temp. varies according to the thermal history of the metal, and it is therefore inferred that more than two **allotropic forms** of cadmium are involved in the change. Electrolytically deposited Cd is unstable γ -cadmium, and this changes into stable α -cadmium in time. The change is attended by a decrease in the e.m.f. of a cell with the cadmium deposited on a Pt spiral as cathode, 12 per cent. cadmium amalgam as anode, and a soln. of cadmium sulphate as liquid. The e.m.f. at 25° fell from $E_\gamma = 0.05047 - 0.0002437(\theta - 25^\circ)$ to $E_\alpha = 0.04742 - 0.000200(\theta - 25^\circ)$ volts after standing several weeks. The difference thus increases as the temp. is lowered. The cadmium which gives the higher voltage is called γ -cadmium, and the one with the lower voltage α -cadmium. F. H. Getman also found that some cells give an e.m.f. of $E_\beta = 0.04862 - 0.000201(\theta - 25^\circ)$ volts a value slightly greater than α -cadmium, and it is concluded that cells with an e.m.f. of 0.050 volt contain γ -cadmium, those with an e.m.f. of 0.048, β -cadmium; and those with an e.m.f. of 0.047 volt, α -cadmium. The difference between the heat of dissolution of a gram-atom of γ - and α -cadmium in 8 per cent. amalgam at 18° is 729 cals., and this represents the heat evolved when γ -cadmium passes into α -cadmium. F. H. Getman gave 37.5° for the transition temp. of α - to β -cadmium. E. Cohen and A. Bruins, and F. H. Getman showed that the supposed allotropic changes cannot be attributed to the adsorption of water of soln. by the metal, but E. Cohen showed that F. H. Getman mistook a change in the cadmium amalgam from a homogeneous to a heterogeneous liquid, and if a recalculation be made the transition temp. α -Cd \rightleftharpoons β -Cd is nearly 60° . E. Cohen and W. D. Helderman showed that γ -Cd is in the metastable state between 0° and 100° . The e.m.f. of the cadmium cells correspond with the metastable transition point γ -Cd \rightarrow α -Cd at 94.8° . For criticisms *vide* allotropic copper. J. N. Greenwood's observations on the annealing and hardness of cadmium led him to infer that there are two modifications of this element— α -Cd, stable between 20° and 65° ; and β -Cd, stable above 65° . Observations were made up to 140° .

F. Stromeyer⁴ found his metal to be harder than tin. A. Saposchnikoff and M. Sacharoff gave 15.9 kgrms. per sq. mm. for the **hardness** of cadmium. J. R. Rydberg gave for the relative hardness of magnesium, zinc, and cadmium, 2.0, 2.5, and 2.0. C. A. Edwards gave 29.0 for Brinell's hardness. P. Ludwik found the curve representing the variation of the hardness with temp. is regular and convex towards the temp. axis whether the metal be slowly or rapidly cooled. H. Siedentopf gave 80.835 to 83.18 mgrms. per mm., or 832.4 dynes per cm. for the **surface tension** of cadmium at 431° ; and $a^2 = 20.633$ to 20.991 per sq. mm. for the **specific cohesion**; G. Quincke gave 70.65 mgrms. per mm., or 815.2 dynes per cm. for the former, and $a^2 = 19.8$ per sq. mm. for the latter—all in an atm. of carbon dioxide. W. Hagemann gave 553 dynes per cm. for the surface tension at 318° , 546.4 dynes per cm. at 350° , and 533.1 dynes per cm. at 412° . T. R. Hogness gave $\sigma = 630 - 0.065(\theta - 320)$ for the surface tension of molten cadmium at θ° . For the coeff. of **viscosity** of molten cadmium at different temp., R. Arpi gave

	349°	406°	466°	506°	550°	603°
Viscosity	0.0144	0.0134	0.0127	0.0118	0.0115	0.0110

For the **diffusion constant** of cadmium in mercury, G. Meyer gave $k = 1.56$ at 15° ; and M. von Wogau, $k = 1.45$ at 87° , and $k = 2.96$ at 99.1° . W. L. Bragg gave 0.160μ for the at. radius of the at. spheres. K. F. Slotte estimated the edge of the mol. cube of liquid and solid cadmium to be 7.1×10^{-9} cms. C. T. Heycock and F. H. Neville estimated the **molecular weight** from the f.p. of soln. of cadmium in sodium, tin, lead, and bismuth. A. Masson found the **velocity of sound** in cadmium to be 2306.6 metres per sec.

F. Stromeyer⁵ found the cadmium he prepared was easily cut with a knife; it was very flexible, and its **ductility** and **malleability** enabled it to be drawn into wires or beaten into plates. Like zinc at 205° , cadmium at 80° becomes brittle, and it can be powdered by rubbing it in a mortar. According to G. Wertheim,

Young's modulus, or the **modulus of elasticity** of cadmium, is from 424×10^6 to 531×10^6 grms. per sq. cm., or 4240 to 5310 kgrms. per sq. mm. at ordinary temp., and he found empirically that the product of Young's modulus into $(M/D)^{\frac{1}{2}}$ is approximately the same for all metals. P. Ludwik made some observations on this subject. W. Sutherland represented the relation between temp. θ° and Young's modulus, E , in grams per sq. cm., by $E/E_0 = 1 - 0.823\theta/T$, where T is the m.p. on the absolute scale, and E_0 is the value of Young's modulus at absolute zero, viz. 1040×10^6 grms. per sq. cm. W. Voigt gave 7070, and E. Grüneisen 5090 to 5240 kgrms. per sq. mm. for the elastic modulus of cast cadmium; and E. Grüneisen, 4.99 dynes per sq. cm. According to the latter, also, the **volume elasticity**, *cubic elasticity*, or *bulk modulus*, is 4.12×10^{11} dynes per sq. cm. E. Grüneisen gave 0.30 for **Poisson's ratio**—that is, the transverse contraction to the longitudinal extension under tensile stress. B. MacNutt and A. Concilio discussed the noises which occur when cadmium is stressed above a certain load. The **compressibility** of cadmium is given by E. Grüneisen as 4200 kgrms. per sq. mm.; and T. W. Richards found the fractional change of vol. caused by one megabar press. between 100 and 500 megabars to be 2.1×10^{-6} ; E. Grüneisen gave 2.4×10^{-6} at 18° . S. Lussana found the coeff. of compressibility of cadmium was 2.88×10^{-6} at 11.5° , and 2.99×10^{-6} at 99° . L. H. Adams, E. D. Williamson, and J. Johnston gave 2.24×10^{-6} per megabar for the compressibility of cadmium at 0 megabar press., and 1.70×10^{-6} at 10,000 megabars press. They represented the change in vol., δv , per c.c. produced when the press. changes from p_0 to p by $\delta v = 1.2 \times 10^{-4} + 2.071 \times 10^{-6}(p - p_0) - 1.75 \times 10^{-11}(p - p_0)^2$. What N. S. Kurnakoff and S. F. Schemtschuschny call the **plasticity**—that is, the press. required to produce a flow of the metal through a given opening at ordinary temp.—is 31.00 kgrms. per sq. mm. W. Spring, and N. Werigen, S. Lewkojeff, and G. Tammann also measured the velocity of flow by pressing the warm metal through an opening. C. J. Burton and W. Marshall found that when suddenly compressed to 300 atm. the temp. of cadmium rises 0.285° and falls 0.293° when the press. is suddenly released.

According to A. Matthiessen,⁶ the **coefficient of linear expansion** of cadmium between 0° and 100° is 0.00003159; and unit vol. at 0° becomes at θ° $1 + 0.00008078\theta + 0.0000001400\theta^2$ vols. H. Fizeau gave 0.00003069 at 40° , or 0.00003102 between 0° and 100° for compressed powdered distilled cadmium; P. Glatzel found 0.00003121; C. Schäfer gave 0.00003060; and W. Voigt, 0.0000247 between 18° and 43° . F. C. Calvert and R. Johnson have also investigated the subject. H. Kopp gave 0.000094 for the coeff. of cubical expansion between 0° and 40° ; and G. Vicentini and D. Omodei found 0.0000948 for solid cadmium at about 315° , and for the molten metal between 318° and 351° , 0.000170. N. E. Dorsey gave 0.00002970 at 10° , and 0.00002302 at -170° . W. Broniewsky gave 0.00009023 for the average coeff. of cubical expansion between absolute zero and the m.p. of cadmium. F. C. Calvert and R. Johnson found that if the **thermal conductivity**, λ , of silver is 100, that of cadmium is 57.7. F. Weber⁷ gave 0.2213 for the absolute conductivity in cal. per cm. per sec. per degree difference of temp. and gave 0.2200 at 0° , and 0.2045 at 100° . W. Jäger and H. Diesselhorst gave 0.2216 at 18° for highly purified cast cadmium, and 0.2149 at 100° ; drawn wire gave a rather higher value. C. H. Lees obtained 0.217 at 18° ; 0.219 at 0° ; 0.228 at -80° ; and 0.239 at -160° . L. Lorenz gave 0.0007046 for the temp. coeff. of the conductivity, and W. Jäger and H. Diesselhorst, -0.38 per cent. The latter also found the temp. conducting power— λ/Ds , where D is the sp. gr., and s the sp. ht.—to be 0.047 at 18° and 0.444 at 100° , with a temp. coeff. of -0.6 per cent. P. W. Bridgman found the thermal conductivity of cadmium increases linearly with press. R. Schott found the thermal conductivity, λ , and the electrical conductivity, K , of cadmium to increase as the temp. is reduced:

	0°	-186°	-250.7°	-251.9°	-252.6°
λ	0.975	1.033	1.833	1.852	1.872
K	0.00146	0.00536	—	—	0.00699

H. V. Regnault⁸ found the **specific heat of cadmium** to be 0.0567; R. Bunsen, 0.0548 between 0° and 100°; W. Voigt, 0.0549 between 18° and 99°. H. Kopp gave 0.0542 at about 37°; A. A. de la Rive and J. Marcet, 0.058 at 10°; F. Weber, 0.0475; and C. J. Burton and W. Marshall, 0.055. E. Heilborn, and L. Sohncke deduced that the sp. ht. of an element with monatomic mol. must decrease with rise of temp., and this agrees with observations on the sp. ht. of mercury. L. Schüz found the sp. ht. of cadmium to be greater between -78° and 20° than between 20° and 100°, but A. Naccari found that the sp. ht. of cadmium steadily rises from 18° to 320°, and he gave 0.0546 at 0°; 0.0570 at 100°; 0.0588 at 200°; and 0.0607 at 300°, or, at θ° , the sp. ht. is $0.0546 + 0.00002367\theta$. U. Behn gave 0.0498 between -186° and -79°; 0.0537 between -79° and 18°; and between 18° and 100°, 0.056; G. W. A. Kahlbaum, K. Roth, and P. Siedler, 0.0559 for ordinary redistilled cadmium, and 0.0560 for cadmium which has been subjected to a high press. F. Streintz gave 5.6 for the at. ht. between -186° and -79°; and 6.0 between 79° and 18°; the temp. coeff. between -30° and -130° is 0.00071. E. H. and E. Griffiths found the at. ht., C_p , to decrease as the temp. falls, thus:

	-223°	-173°	-133°	-93°	-53°	13°	7°	47°	107°
C_p	3.46	5.37	5.79	5.93	6.04	6.14	6.19	6.29	6.44

W. H. Rodebush gave for the at. ht., C_p , 4.69 at -200°; 4.91 at -193°; 5.15 at -183°; 5.32 at -173°. A. Naccari represented his results for the sp. ht. of cadmium at θ° , by $0.0546(1 + 0.00044310\theta)$. R. C. Tolman gave 39.8 for the **entropy** of cadmium at 25°, G. N. Lewis and co-workers, 39.79 (gas), or solid 11.80.

The **melting point** of cadmium was found by A. D. van Riemsdijk,⁹ and by F. Rudberg to be 320°; by A. Ditte, 315°; by B. Wood, 315°-316°; by C. C. Person, and H. L. Callendar, 320.7°; by F. Nies and A. Winkelmann, 310°-320°; by H. Becquerel, 315.8°; by G. Vicentini and D. Omodei, 318°; by E. H. Griffiths, 321.67°; by H. Siedentopf, 312°; by A. L. Day and E. T. Allen, 320.7° to 321.7°; by C. Schäfer, 320°; by L. Holborn and A. L. Day, 321.7°; by N. S. Kurnakoff and N. N. Pushin, 321.0°; C. W. Waidner and G. K. Burgess, 320.39° to 321.01°; A. L. Day and R. B. Sosman, $320.0^\circ \pm 0.3^\circ$; and by L. Holborn and F. Henning, 320.92°. Other determinations have been made in connection with the fusion curves of binary mixtures by C. T. Heycock and F. H. Neville, H. Gautier, O. Boudouard, G. Masing and G. Tammann, H. C. Bijl, K. Lewkonja, R. Sahmen, M. Kobayashi, A. Stoffel, G. Hindrichs, D. P. Smith, C. H. Mathewson, G. Voss, W. Treitschke, etc. According to K. Scheel, W. Guertler and M. Pirani, and L. I. Dana and P. D. Foote, the best representative value may be taken to be 321°. H. Ramage compared the m.p. of the metals beryllium, magnesium, zinc, cadmium, and mercury. M. Lémery, J. von Panayeff, and H. F. Wiebe have also discussed the relations of the m.p. of these elements. W. Spring claimed to have united two cylinders of cadmium by warming them for 5 hrs. at 295°. J. Johnston and L. H. Adams found the m.p. of cadmium was depressed $d\theta/dp = 0.00629^\circ$ per atm. C. C. Person gave 13.66 Cals. per kgrm. or 1.54 Cals. per gram-atom for the **heat of fusion** of cadmium; J. Johnston and L. H. Adams gave 13.7 cals. per gram. A. C. Egerton, and J. W. Richards have made observations on this subject. F. S. Mortimer gave 23.4 Cals. for the latent **heat of vaporization**.

C. Barus, and O. Ruff and B. Bergdahl measured the **vapour pressure** of cadmium in mm. of mercury at different temp., and the former found:

	549°	565°	620°	667°	702°	724°	745°	760°	770°
Vap. press.	22	26	75	157	262	355	489	624	766

J. W. Richards also calculated the following values for the vap. press. in mm. of mercury:

	183°	300°	367°	473°	600°	700°	780°	934°	1652°
Vap. press.	0.0002	0.050	0.478	9.23	75.75	300	760	3230	123120

The vap. press. curve of cadmium is indicated in Fig. 9. A. C. Egerton represented the vap. press., p , of cadmium at the absolute temp., T , by $p=5.27 \times 10^{13} T^{-1} e^{2.77 \times 10^4/RT}$ dynes per sq. cm., or $\log p=10.5979-0.5 \log T-6060T^{-1}$ mm. The slope of the vap. press. curve of cadmium at the m.p. is 3.70×10^{-3} mm. J. A. M. van Liempt represented the vap. press., p , of cadmium between 822° K. and 1055° K. by the formula $\log p=-5977/T+5.65$ atm., where T denotes the absolute temp.; and he represented the sublimation curve of cadmium by the formula $\log p=-6313/T+6.21$. F. A. Henglein made some observations on this subject. C. Barus' formula is $\log p=2063-7443T^{-1}-3.868 \log T$; and H. Braune's, $\log p=-5753T^{-1}-1.28 \log T+12.282$. J. A. M. van Liempt gave 25.82 for **Trouton's constant**; and H. Braune, 7.50 for the **chemical constant**.

According to B. Wood,¹⁰ cadmium volatilizes at a temp. somewhat over 315° , "giving off orange-yellow coloured suffocating fumes, which, when inhaled too freely, leave a disagreeable, sweetish, styptic sensation upon the lips, and an intolerable and persistent brassy taste in the mouth, with constriction in the throat, heaviness in the head, and nausea." W. Spring supposed cadmium volatilizes between 295° and 300° because it can alloy with copper at that temp. C. J. Hansen found that cadmium evaporates appreciably at 429° . F. Krafft found that cadmium evaporates appreciably at 322° , and boils in vacuo at 450° when exposed to green cathode rays. E. Demarçay, and A. Schuller observed the vaporization at 160° . According to F. Krafft and L. Bergfeld, the difference between the temp., 156° , at which vaporization begins in vacuo, and the b.p., 450° , in vacuo, is approximately equal to the difference between the b.p. of the metal in vacuo and at atm. press. 749° . T. Turner and co-workers studied the effect of inert gases at different press. on the rate of volatilization of cadmium. K. Bennewitz measured the **rate of evaporation** of cadmium in vacuo. H. J. S. Sand, J. Stark and S. Kinoshita, and J. Stark and R. Kuch made a **cadmium vapour lamp** analogous to the mercury vapour lamp. F. Krafft found drops of cadmium exhibited Leidenfrost's phenomenon. C. J. Hansen found the **boiling point** of cadmium to be 749° at atm. press., and 450° in vacuo. H. St. C. Deville and L. Troost gave 860° , which on correction becomes 815° , for the b.p. of cadmium. T. Carnelley and W. C. Williams gave 763° to 772° ; E. Becquerel, 746° ; C. Barus, 782° ; W. R. Mott, 778° ; H. le Chatelier, 770° ; O. Ruff and B. Bergdahl, 785° ; J. A. M. van Liempt, 786° ; D. Berthelot, 778° ; O. H. Weber, 770° to 780° . C. Barus gave for the b.p. of cadmium at different press. in mm. of mercury :

Press.	.	.	.	0	22	105	262	489	517	656	756
B.p.	.	.	.	444°	549°	639°	702°	745°	750°	766°	772°

D. Berthelot represented the b.p. of cadmium by $788+\frac{1}{5}(p-760)$, where p denotes the press. but slightly removed from normal atm. press. in mm. of mercury. According to F. Krafft and P. Lehmann, the b.p. of cadmium increases 5° for a rise of 80° mm. press. W. Sutherland calculated values of $dp/d\theta$ from C. Barus' vap. press. measurements, and showed that the latent **heat of vaporization** of liquid cadmium is 29.6 Cals. per gram-atom. A. Wehnelt and C. Musceleanu, and E. van Aubel found the latent heat of vaporization of zinc is 181 Cals. per kgrm., J. W. Richards gave 216 Cals. per kgrm., and J. A. M. van Liempt, 27,360 cals. at the b.p. C. C. Person gave 1540 cals. for the heat of sublimation. E. Beckmann and O. Liesche measured the b.p. of cadmium amalgams and found the results agreed with the monatomic condition of the metal at these temp. W. G. Duffield gave 4.0×10^4 cms. per sec. for the velocity of the mols. projected from boiling cadmium.

According to M. Knudsen, cadmium vapour condenses on a clean glass or mica plate when the temp. is between -183° and -78° , but above the latter temp., the vapour is partly retained by and partly repelled from the surface. R. W. Wood found that cadmium may condense as a thin metal film when the temp. is below -100° , but above that temp. it deposits aggregates of metal which appears to be clusters of crystals. A. C. Egerton has also made observations on this subject. According

to J. W. Richards, if the partial press. of cadmium vapour in a condenser is 380 mm., no metal will condense until the temp. of the gases is reduced to 720° . This temp. may thus be compared with the dew-point of air—*vide* zinc fume.

P. Drude¹¹ found the **index of refraction** of metallic cadmium to be $\mu=1.13$ for $\lambda=0.589\mu$; the **absorption index** $k=501$; and the **reflecting power** $R=85$ per cent. W. W. Coblentz gave for the reflecting power R :

λ	.	.	.	1.0	2.0	4.0	7.0	10.0	12.0 μ
R	72	87	96	98	98	99

Plane polarized light reflected from a polished surface is generally elliptically polarized, and for a certain angle, the **angle of principal incidence**, ϕ , $79^{\circ} 57'$, the change is 90° , and if the plane polarized incident beam has a certain azimuth, **angle of principal azimuth**, ψ , $38^{\circ} 53'$, circular polarized light results. H. Knoblauch gave 76.65° for the polarization angle of heat rays, and 4.087 for the index of refraction; and for yellow rays respectively 70.00° and 2.747 . C. Cuthbertson and E. P. Metcalfe gave for the refractivity $(\mu-1) \times 10^6 = 2780$ for cadmium vapour with $\lambda=518.3\mu\mu$; 2725 for $\lambda=546\mu\mu$; 2675 for $\lambda=589.3\mu\mu$, and $\lambda=656.3\mu\mu$. L. Natanson obtained 1337 for sodium light. C. V. Kent measured the effect of temp. on the optical properties of molten cadmium. J. H. Gladstone's value for the **refraction equivalent** is 13.1 , and W. J. Pope's, 16.53 for the *D*-ray. J. Kanonnikoff, and W. Orloff have made observations on this subject. B. Pogany measured the **Faraday effect**, that is, the **rotation of the plane of polarization** of thin films of cadmium. S. Procopiu found that toluene has a positive birefringence, but if finely powdered cadmium is suspended thereon, the birefringence is negative. Similarly with benzene, etc.

J. A. Wilkinson¹² observed a bright greenish-yellow **fluorescence** during the action of chlorine on cadmium but none with bromine or iodine; a yellow fluorescence during the action of oxygen or sodium peroxide; and a white or bluish-white fluorescence during the action of a persulphate. E. Wiedemann and G. C. Schmidt also examined the phosphorescence of cadmium salts in the cathode rays. J. S. van der Lingen studied the fluorescence of cadmium vapour. J. J. Thomson, H. G. J. Moseley, E. Hjalmar, and C. G. Barkla and C. A. Sadler have examined the absorption coeff. of cadmium under the influence of the secondary radiations from **X-rays**; and M. Hurmuzescu found that cadmium is less active than zinc, but more active than magnesium, aluminium, or tin. The high frequency or X-ray spectrum has been studied by E. Friman, D. Coster, etc. J. A. Becker investigated the effect of a magnetic field on the absorption of X-rays. N. R. Campbell has studied the ionization of air by the metal; and H. Greinacher, the radioactivity of cadmium. H. R. von Traubenberg found the range of the **α -rays** in cadmium to be 24.2×10^{-4} cms. F. Streintz, B. L. Vanzetti, H. Muraoka and M. Kasuya, F. Streintz and O. Strohschneider, and N. Piltchikoff have studied the **photographic effects** of cadmium on silver bromide, and potassium iodide. E. Légrady attributes the effect to a reaction with water vapour whereby H^+ -ions are produced, but no hydrogen peroxide is formed as assumed by W. Merckens—*vide* copper, and zinc. The elements arranged in the order of their **photoelectric effect** have been given in connection with zinc. R. Hamer found the limiting frequency for the photoelectric effect with cadmium to be 3130 ± 50 .

FIG. 16.—The Spark Spectrum of Cadmium.

The **spark spectrum** of cadmium was first noted by C. Wheatstone.¹³ Observations by A. Masson, and T. R. Robinson did not advance the study very far. G. Kirchhoff measured some lines and compared the results with the measurements

of the Fraunhofer lines of the solar spectrum. Measurements have been made by R. Thalén, W. Huggins, L. de Boisbaudran, J. N. Lockyer, W. N. Hartley, G. D. Liveing and J. Dewar, H. Becquerel, G. Ciamician, G. A. Hemsalech and A. de Gramont, E. Carter, J. S. Ames, H. Kayser and C. Runge, A. A. Michelson, A. Fowler and H. Payn, etc. The more important of the 74 lines in the arc spectrum of cadmium, expressed in 10^{-8} cm. units, in air at 15° and 760 mm., are: 3261.3404, 3406, 3466, and 3611 in the ultra-violet; 3982 in the violet; 4413, 4678, and 4799.908 (β) in the blue; 5085.822 (α), 5155, 5338, and 5379 in the green; and 6438.470 (γ) in the red. The triplet on the scale at 80, 95.4, and 102.8 in the spectrum of cadmium corresponds with the triplet at 94.6, 100.05, and 102.6 in the spectrum of zinc. The α -, β -, and γ -lines are characteristic. With a more intense sparking, the α -line becomes weaker, and lines appear at 5379 and 5338. A. A. Michelson proposed referring measurements of wave-lengths of spectral lines to the α -, β -, and γ -cadmium lines. The red line at 6438 and the green line at 5086 serve as standards for absolute measurements. F. Brasack claimed to be able to detect 0.0004 mgrm. of cadmium in the spectrum of the spark from metal electrodes; and E. Cappel, 0.000056 mgrm. W. Schuler found the characteristic lines of cadmium are no longer visible with 0.0004 mgrm. of cadmium chloride; 0.0002 mgrm. of cadmium bromide, iodide, nitrate, or sulphate. R. C. Dearle, and F. M. Walters measured the infra-red spectrum of cadmium.

The spectral lines of the magnesium, zinc, and cadmium family of elements furnish a number of **line-series**, as illustrated in Fig. 3, 4. 29, 4. H. Kayser and C. Runge represented the first two series of triplets in the spectrum of cadmium by the formulæ:

FIRST SERIES.

$$10^4\lambda^{-1}=40755.21-128635n^{-2}-1289619n^{-1}$$

$$10^4\lambda^{-1}=41914.60-128635n^{-2}-1289619n^{-1}$$

$$10^4\lambda^{-1}=42456.64-128635n^{-2}-1289619n^{-1}$$

SECOND SERIES.

$$10^4\lambda^{-1}=40797.12-126146n^{-2}-555137n^{-1}$$

$$10^4\lambda^{-1}=41968.80-126146n^{-2}-555137n^{-1}$$

$$10^4\lambda^{-1}=42510.58-126146n^{-2}-555137n^{-1}$$

which account for nearly half of the lines in the arc-spectrum of cadmium. Several intense lines are not included in the formulæ, *e.g.* the line 2288.10 which, according to J. Stack and S. Kinoshita, is the most intense of the cadmium lines at a low temp. The line-series of the cadmium spectrum have been studied by W. N. Hartley, J. S. Ames, J. R. Rydberg, H. Kayser and C. Runge, C. Runge and F. Paschen, L. Janicki, A. Grünwald, C. de Watteville, J. de Kowalsky and P. Joye, E. Hulthén and E. Bengtsson, S. Procopiu, A. Kratzer, H. Crew, A. Fowler and H. Payn, O. von Bayer, F. A. Saunders, P. G. Nutting, etc. C. Fabry studied the satellites in the cadmium spectrum. J. M. Eder and E. Valenta, W. N. Hartley, C. de Watteville, E. Cappel, etc., studied the effect of *temperature* on the sensitiveness of the spectral reactions of zinc; the effect of *pressure* was investigated by A. Kalähne, M. Ritter, F. L. Mohler, W. J. Humphreys, C. Keller, etc.; the effect of *hydrogen* and *nitrogen* was studied by L. Arons; and H. Finger, and B. de la Roche, the effect of the gaseous medium on the spectrum. A. Hagenbach and H. Schumacher studied the line spectrum of cadmium in the electrodeless ring discharge.

The **flame spectrum** of cadmium consists of lines and bands which have a complicated structure. The lines include the 5086, 4800, 4678, and 3261. H. Ramage could not find the line 2288 in the oxy-hydrogen flame spectrum. The flame spectrum has been studied by A. Mitscherlich, J. N. Lockyer and W. C. Roberts, A. Gouy, J. M. Eder, W. N. Hartley, W. N. Hartley and H. Ramage, C. de Watteville, etc. The **ultra-violet spectrum** was investigated by G. G. Stokes, W. H. Miller, J. L. Soret, W. N. Hartley and W. E. Adeney, L. and E. Bloch, L. Bell, H. Deslandres, G. D. Liveing and J. Dewar, J. M. Eder, J. M. Eder and E. Valenta, G. Berndt, C. Runge and F. Paschen, R. A. Sawyer, E. Néculea, R. W. Wood and D. V. Guthrie, F. Exner and E. Haschek, J. Stark and S. Kinoshita, E. Mascart, etc. J. J. Dobbie and J. J. Fox found cadmium vapour has a number of sharply defined absorption bands in the ultra-violet. E. Hulthén studied the band spectrum of cadmium.

The **ultra-red spectrum** was investigated by V. Schumann, F. Paschen, H. Becquerel, etc. The **Zeeman effect** was investigated by A. A. Michelson, P. Zeeman, J. S. Ames, R. F. Earhart and H. M. Reese, T. Preston, J. C. Shedd, H. M. Reese, H. Ramage, W. H. Miller, C. Runge, F. Paschen and C. Runge, etc. Cadmium salts form colourless soln. which do not give an **absorption spectrum** alone or with tincture of alkanna. T. Retschinsky found solid cadmium chloride gives an absorption spectrum. J. Elster and H. Geitel have studied the **photoelectric effect** with cadmium. J. S. van der Lingen studied the electrodeless discharge in cadmium vapour. F. L. Mohler and co-workers found the **resonance potential** of cadmium vapour to be 3.95–5.35 volts, and the **ionization potential** to be 9.0 volts; for the latter, J. C. McLennan and J. F. T. Young obtained 9.0 volts. K. T. Compton found 2.66–3.96 volts for the minimum ionization potential. M. N. Saha has made observations on this subject. B. E. Moore studied the excitation stages in the arc spectrum of cadmium.

The **electrical conductivity** of cadmium has been measured by A. Matthiessen,¹⁴ who found that if hard silver has a conductivity of 100, at 0°, that of cadmium is 22.10; E. Becquerel found 24.58; J. R. Benoit, 22.5; and A. Matthiessen and A. von Bose, 23.72; the latter also obtained $1-0.0036871\theta + 0.000007575\theta^2$ for the conductivity at θ° ; and J. R. Benoit, $1+0.004264\theta + 0.000001765\theta^2$. F. Weber found the specific conductivity to be 0.001461; W. Jäger and H. Diesselhorst gave for cadmium with less than 0.05 per cent. of lead, zinc, and iron, at 18°, 13.13×10^4 rec. ohms, and at 100°, 9.89×10^4 rec. ohms, while for the less pure metal, they obtained 13.25×10^4 and 10.18×10^4 rec. ohms respectively at 18° and at 100°; for the two varieties of cadmium the **electrical resistance** at θ° was found to be respectively $1+0.00425\theta$, and $1+0.0040\theta$. L. Lorenz obtained 14.41×10^4 rec. ohms at 0°; G. Mayrhofer, 14.7×10^4 rec. ohms at 0°; and the latter found that the conductivity increases 1.3 per cent. when the temp. was raised to 130°, and he gave for the specific conductivity at θ° , $1-0.00378\theta$. J. Dewar and J. A. Fleming found the electrical resistance R of cadmium in microhms to be:

θ°	182.2°	91.10°	18.8°	1.00°	-46.2°	-81.9°	-197.1°
R	18.367	13.843	10.980	10.064	0.286	6.945	2.952

A. Eucken and G. Gehlhoff gave 7.76 microhms at 0°; 5.45 at -79°; and 1.98 microhms at 190°. Some results by R. Schott are indicated in connection with thermal conductivity. E. F. Northrup and V. A. Suydam found, for the resistance R in microhms:

θ°	300°	325°	350°	400°	500°	600°	700°
R	16.52	33.76	33.60	33.70	34.12	34.82	35.78

and they gave the ratio 1.97 for the resistivity of the liquid at the m.p. (318°), viz. 33.77 microhms, to the value for the solid at the m.p. of zinc—viz. 17.1 microhms. G. Tammann and K. Dahl studied the relation between the resistance and structure of cadmium-zinc alloys. G. Vassura found the conductivity of cadmium at the m.p. 318°, before and after fusion, to be respectively 5.69×10^4 and 2.88×10^4 microhms, and G. Vicentini and D. Omodei gave for fused cadmium at the m.p. 318° , 2.99×10^4 microhms.

F. Streintz found the temp. coeff. of the electrical resistance of cadmium between 18° and 100° to be $dR/d\theta = 425 \times 10^{-5}$; L. Holborn gave 424×10^{-5} per degree between 0° and 100°. P. W. Bridgman, and B. Beckman measured the effect of pressure and temp. on the electrical resistance of cadmium; the former obtained for 0 and 1200 kgrms. per sq. cm.,

	0°	25°	50°	75°	100°
Resistance	1.0000	1.1012	1.2057	1.3133	1.4240
Press. coeff. { 0 kgrm.	-0.0 ₅ 1063	-0.0 ₅ 1082	-0.0 ₅ 1095	-0.0 ₅ 1102	-0.0 ₅ 1106
{ 12,000 kgrms.	-0.0 ₅ 746	-0.0 ₅ 765	-0.0 ₅ 778	-0.0 ₅ 786	-0.0 ₅ 790
{ Average	-0.0 ₅ 8940	-0.0 ₅ 9104	-0.0 ₅ 9212	-0.0 ₅ 9257	-0.0 ₅ 9270

The average temp. coeff. from 0° to 100° at 0 kgrm. press. is 0.00424; W. Jäger

and H. Diesselhorst gave 0.00396 to 0.00421; and B. Beckman, 0.00425. G. Fäe found the influence of *magnetization* on the electrical resistance of cadmium to be uncertain. N. Dagostino found that the electrical resistance is increased by transverse magnetization, and L. Grunmach said that the increase is greater with cadmium than with zinc, copper, silver, gold, tin, lead, platinum, palladium, and tantalum.

A. Coehn and A. Lotz found that cadmium in vacuo is negatively charged against glass. W. Hankel¹⁵ found that if the difference of potential of zinc and copper be 200, that of filed cadmium and copper is 175, and of cleaned cadmium, 181. The **Volta effect** was attributed by E. Warburg and H. Greinacher to a condensed layer of water because the difference of potential between cadmium and radiotelluro-copper is -0.540 volt, and when thoroughly dried, -0.015 , and when exposed to the air of a room, -0.719 . W. Ostwald found that cadmium, like zinc, is electronegative towards acids; and W. Hankel that it is electronegative towards water. W. Spring found that cadmium which has been strongly compressed shows a difference of potential of 0.20 millivolt towards the annealed metal.

Cadmium is thermoelectrically positive. A. Seebeck¹⁶ found that cadmium is nearer than zinc to the positive end of the thermoelectric series of metals, but, according to W. Hankel, it is less positive than iron or antimony, and, according to B. Bachmetjeff, it is more positive than indium. N. A. Hesehus found that when cadmium is warmed in a circuit of the metal, a current flows from the warm to the cold part, and the e.m.f. is smaller with cadmium than with antimony, and larger than with zinc, silver, copper, or brass. For the *cadmium-platinum couple* with the cold and hot junctions respectively at 0° and 100° , W. Jäger and H. Diesselhorst gave 0.85 millivolt; J. Dewar and J. A. Fleming, 0.92 millivolt; K. Noll, 0.88 millivolt; W. H. Steele, 0.90 millivolt; and E. Wagner, 0.92 millivolt. K. Noll found the **thermoelectric force**, or the **Seebeck effect**, of hard-drawn *cadmium-mercury couple* between 0° and 100° to be 875.09 millivolts, and with annealed cadmium, 859.74 millivolts. W. H. Steele, and J. Dewar and J. A. Fleming found the thermo-electric force of a *cadmium-lead couple* with one junction at 0° and the other at θ° is, in C.G.S. units:

θ	100.2°	61.2°	8.1°	-4.0°	-34.6°	-85.2°	-128.8°	-205.0°
E.m.f.	48020	24600	2220	-1180	-8560	-17200	-21450	-26940

P. G. Tait found that with the cadmium-lead couple, the thermoelectric force at θ° is $2.63 + 0.0424\theta$, and the neutral point is -62° . P. W. Bridgman gave $E = (12.002\theta + 0.1619\theta^2) \times 10^{-6}$ volts for the Seebeck effect with cadmium and lead at atm. press. G. Borelius and F. Gunneson measured the Thomson effect between -176° and 94° . A. Heil measured the e.m.f. of a *cadmium-cupro-nickel couple* and found for $\theta^\circ = 230^\circ$, $+0.0117$ volt. W. Jäger and H. Diesselhorst found for the *cadmium-copper couple*, $+2.3$ microvolts per degree between 0° and 100° ; for the *cadmium-iron couple*, $+6.3$ microvolts; and for the *cadmium-constantin couple*, 49.4 microvolts. P. Cermak also studied the last-named thermocouple; and A. Abt, the thermoelectric force between cadmium and copper, or carbon. For the Seebeck effect with a couple composed of one branch of uncompressed cadmium and the other of cadmium compressed to a press. p kgrms. per sq. cm., with the junctions at 0° , P. W. Bridgman found

			10°	20°	40°	60°	80°	100°
p {	2,000		$+0.14$	$+0.42$	$+1.38$	$+2.82$	$+4.74$	$+7.12$
	6,000		0.88	2.10	5.48	8.88	15.14	21.16
	12,000		3.16	6.68	14.72	23.92	34.20	45.56

The effect is large and positive rising with temp. and press. The results are much affected by hysteresis, corresponding with an incomplete state of internal equilibrium. The **Peltier effect**, that is, the heat produced by a current at the junction of copper and cadmium, in cal. per ampere-hour—*vide* magnesium—is -0.62 , according to H. Jahn, and -0.46 , according to E. P. le Roux; and the latter gave -0.45 millivolt for the Peltier e.m.f.; H. Jahn gave -0.72 millivolt; and E. Edlund, -0.16

millivolt. For the Peltier effect, σ , with cadmium and lead, P. W. Bridgman gave $\sigma = 0.3238(\theta + 273) \times 10^{-6}$ volts per degree, and for the Peltier effect between compressed and uncompressed cadmium, in joules per coulomb $\times 10^6$:

				0°	20°	40°	60°	80°	100°
p	2,000	.	.	+3.8	+10.0	+18.8	+28.0	+38.1	+48.5
	6,000	.	.	18.6	41.0	61.6	80.7	99.8	118
	12,000	.	.	81.3	108	135	162	191	221

The effect is positive and rises with temp. and press. For the **Thomson effect**, excess in compressed over uncompressed cadmium, in joules per coulomb per degree $\times 10^8$, P. W. Bridgman found:

				0°	20°	40°	60°	80°	100°
p	2,000	.	.	+16	+35	+41	+37	+35	+45
	6,000	.	.	109	94	78	70	67	63
	12,000	.	.	105	99	94	90	90	93

The effect is positive and rises with temp. at low press., but falls at high press. E. Wagner also made some observations on this subject with press. up to 300 kgms. per sq. cm. G. Borelius and F. Gunneson found the Thomson effect in microvolts per degree to be 9.8 at 400° K., 7.1 at 300° K., 0.55 at 190° K., 0.0 at 150° K., and -0.65 at 110° K. A. E. Caswell found for the coeff. of the Hall effect 8.50×10^{-13} at 42°; and 11.67×10^{-13} at 49.3°; for the coeff. of the Ettinghausen effect, 5.96×10^{-8} at 51.2°; for the coeff. of the Nernst effect, 0 at 39.4°; and for the coeff. of the Seebeck effect, 1.87×10^{-7} at 39.4°.

W. G. Horsch¹⁷ measured the potential of the amalgamated and ordinary **cadmium electrode** in the combinations $\text{Cd}_{\text{amalgam}} | \text{CdCl}_2, \text{AgCl} | \text{Ag}$, and $\text{Cd} | \text{CdCl}_2 | \text{Cd}_{\text{amalgam}}$. E. Cohen and co-workers measured the effect of *pressure and temperature* on the electrode. The potential of cadmium against aq. soln. of various *cadmium salts* has been measured by B. Neumann, W. Nernst, U. Sborgi and A. Donati, W. Ostwald, G. Carrara and L. d'Agostini, F. Streintz and O. Strohschneider, N. R. Dhar, N. T. M. Wilshire, F. M. G. Johnson and N. T. M. Wilshire, F. Förster, C. Immerwahr, L. Kahlenberg, S. Labendzinsky, H. Euler, etc.—*vide* cadmium amalgam. The effect of temp. on the difference of potential between cadmium and aq. soln. of its salts was measured by E. Bouty and A. Gockel. F. M. G. Johnson and N. T. M. Wilshire measured the potential of cadmium against soln. of cadmium nitrate in *liquid ammonia*; R. Luther, and G. Carrara and L. d'Agostini, with soln. of cadmium salts in *methyl and ethyl alcohols*; and L. Kahlenberg, with soln. of cadmium salts in aq. *pyridine*. R. Beutner, and F. Haber measured the difference of potential with cadmium and its compressed solid salts; and J. Brown, with fused cadmium chloride.

G. Magnanini measured the difference of potential, in centivolts, of zinc in a normal soln. of sulphuric acid against cadmium in a soln. containing n mols of the following salts per litre, and found $\frac{1}{2}n\text{-H}_2\text{SO}_4$, 36.6 centivolts; $n\text{-NaOH}$, 19.5; $n\text{-KOH}$, 15.5; $\frac{1}{2}n\text{-Na}_2\text{SO}_4$, 35.6; $n\text{-Na}_2\text{S}_2\text{O}_3$, 24.1; $n\text{-KNO}_3$, 31.9; $n\text{-NaNO}_3$, 32.3; $\frac{1}{2}n\text{-K}_2\text{CrO}_4$, 42.8; $\frac{1}{2}n\text{-K}_2\text{Cr}_2\text{O}_7$, 61.1; $\frac{1}{2}n\text{-K}_2\text{SO}_4$, 34.7; $\frac{1}{2}n\text{-(NH}_4)_2\text{SO}_4$, 37.1; $\frac{1}{2}n\text{-K}_4\text{FeCy}_6$, 33.6; $0.167n\text{-K}_3\text{FeCy}_6$, 80.8; $n\text{-KC}_2\text{S}$, 32.5; $\frac{1}{2}n\text{-Sr(NO}_3)_2$, 38.3; $\frac{1}{2}n\text{-Ba(NO}_3)_2$, 39.3; $\frac{1}{2}n\text{-KClO}_3$, 39.9; $0.167n\text{-KBrO}_3$, 40.7; $n\text{-NH}_4\text{Cl}$, 32.4; $n\text{-KF}$, 22.5; $n\text{-NaCl}$, 31.9; $n\text{-KBr}$, 31.7; $n\text{-KCl}$, 32.1; $\frac{1}{2}n\text{-Na}_2\text{SO}_3$, 28.7; soln. of bromine in sodium hydroxide, 41.6; $n\text{-tartaric acid}$, 39.7; $\frac{1}{2}n\text{-tartaric acid}$, 41.3; and $\frac{1}{2}n\text{-potassium sodium tartrate}$, 31.5.

Cadmium is strongly electropositive, and, according to J. C. Poggendorff,¹⁸ it becomes less electropositive by amalgamation. Early observations on the relation of cadmium to other metals are indicated in connection with zinc. A. P. Laurie found cadmium to be electronegative towards zinc in contact with a soln. of *sodium chloride*. J. Tafel, and J. Tafel and B. Emmert measured the difference of potential of cadmium against platinum in *sulphuric acid*; and J. C. Poggendorff measured the difference of potential of cadmium against bismuth, palladium, iron, mercury, and amalgamated cadmium in dil. sulphuric acid. A. P. Laurie measured the

difference of potential of zinc against platinum in soln. of *cadmium iodide and iodine*; J. Regnault, of cadmium against carbon in soln. of *potassium iodide and iodine*; and F. Streintz, of cadmium against zinc, and copper in soln. of *cadmium nitrate*; of cadmium against magnesium, zinc, tin, cobalt, copper, silver, mercury, and bismuth in soln. of *cadmium sulphate*; of cadmium against zinc, and copper in soln. of *cadmium chloride*. C. R. A. Wright and C. Thompson, and F. M. G. Johnson and N. T. M. Wilmore measured the difference of potential of cadmium against amalgamated zinc, magnesium, aluminium, copper, silver, mercury, and lead, in soln. of the nitrate, sulphate, chloride, bromide, or iodide. L. Kahlenberg measured the difference of potential of cadmium against zinc, and silver in pyridine soln. of cadmium nitrate. E. F. Herroun, of cadmium in a soln. of cadmium sulphate or chloride against tin in a soln. of *stannous chloride*.

The **heat of ionization** of cadmium per valence is given by W. Ostwald¹⁹ as 8300 cal.; H. Jahn gives 16·12 Cals. for Cd⁺⁺-ions. The **transport numbers** of cadmium ions have been measured by K. Drucker, F. Kohlrausch, F. J. Wershoven, O. Grotrian, W. Hittorf, J. W. McBain, G. Kümmel, V. Gordon, R. Lenz, G. Carrara, E. Rieger, B. D. Steele, etc. The **velocities of the ions**, *V*, have been measured by F. Kohlrausch, and A. E. Garrett. The velocities, *V*, in mm. per sec. of the cation of soln. containing *n* mols of cadmium sulphate per litre are :

<i>n</i>	:	:	:	:	0·1	0·04	0·02	0·01	0·005	0·0025
<i>V</i>	:	:	:	:	0·023	0·029	0·026	0·036	0·045	0·051

R. Lenz, W. Hampe, W. Hittorf and F. J. Wershoven investigated the conductivity of alcoholic soln. W. P. Davey gave 0·95 A. for the **atomic radius** of the cadmium ion in cadmium sulphide, and 1·11 A. in the oxide. The **electrochemical equivalent** corresponds with the deposition of 2·0886 grms. of cadmium per ampère-hour.

The **decomposition voltages** of aq. soln. of many cadmium salts—sulphate, phosphate, cyanide, chloride, nitrate, and complex salts—have been determined by many investigators²⁰—M. le Blanc, H. Freudenberg, H. E. Patten and W. R. Mott, J. E. Root, C. Coffetti and F. Förster, A. Brunner, A. Schweitzer, etc. C. C. Garrard investigated molten cadmium salts. P. A. Favre, and H. Jahn compared the thermal and electrical energy required for the decomposition of these salts. The electrolytic **solution pressure** of cadmium in aq. soln. has been investigated by C. R. A. Wright and C. Thompson,²¹ F. Braun, W. Ostwald, B. Neumann, H. Jahn, O. Sackur, G. Carrara and L. d'Agostini, etc. The constant works out at approximately 10⁷ atm. H. C. Jones and A. W. Smith estimate the soln. press. of zinc in alcohol to be approximately 10⁸ times smaller than in water. The **overvoltage** of hydrogen on cadmium electrodes in *N*-H₂SO₄ is approximately 0·48 volt. The subject has been investigated by J. Tafel,²² W. A. Caspari, N. R. Dhar, E. Müller, A. Coehn and Y. Osaka, etc. The **polarization** of cadmium electrodes has been investigated by H. Jahn, M. le Blanc, A. Coehn and Y. Osaka, O. H. Weber, etc. J. S. van der Lingen studied the **electrodeless discharge** in cadmium vapour. B. Pogany sought for the **Faraday effect**—the rotation of the plane of polarization in a magnetic field—with thin films of cadmium. According to H. Schönz cadmium becomes passive in contact with platinum in nitric acid, of sp. gr. 1·47, but not in dil. nitric acid. U. Sborgi and P. Marchetti have studied the anodic behaviour of cadmium in a sat. soln. of lithium chloride in acetone. The **electrolytic valve-action** of cadmium has been discussed by A. Günther-Schulze,²³ and W. Holtz in aq. salt soln.

The **electric discharge** between cadmium electrodes has been studied by C. E. Guye and A. Bron,²⁴ F. Müller, A. Pospiehoff, and C. A. Skinner. The potential gradient of the arc was investigated by V. L. Chrisler; the **disintegration of cadmium electrodes** by W. Crookes, G. Grandquist, and V. Kohlschütter and R. Müller. K. Honda found that the **magnetic susceptibility** of cadmium at 18° is $-0·17 \times 10^{-6}$ units of mass, and at 700°, $-0·15 \times 10^{-6}$ units.

§ 6. The Chemical Properties of Zinc and Cadmium

G. Williams¹ found that zinc can occlude 38 times its vol. of **hydrogen**; but A. Sieverts, J. Hagenacker, and W. Krumbhaar stated that no hydrogen is dissolved by molten zinc; and G. Neumann and F. Streintz, that electrolytic zinc occludes but traces of hydrogen. W. Heald found zinc and cadmium films do absorb some hydrogen gas. A. Fowler and H. Payn obtained spectral indications which could be interpreted by the assumption that *cadmium hydride* is formed. B. Delachanal found that when 100 grms. of ordinary zinc are heated in an evacuated porcelain tube, the **occluded gas** contains 18.15 c.c. of hydrogen, 1.65 c.c. of carbon monoxide, and 0.50 c.c. of carbon dioxide. M. Guichard noted that zinc after five sublimations under reduced press. gives off 2 c.c. of occluded gas per 100 grms. of metal; and the occluded gas in cadmium, which has been purified by repeated sublimation, has a vap. press. of approximately 0.01 mm. H. Pauli stated that the sp. gr. of zinc may fall from 6.52 to 3.5 owing to the occlusion of gas. C. A. Skinner obtained hydrogen by using freshly polished zinc as cathode in the helium discharge tube, and nitrogen, by using it in an evacuated discharge tube.

L. N. Vauquelin believed that he had prepared *zinc hydride* or *zincuretted hydrogen* by igniting zinc blende with one-fourth of its wt. of charcoal. He also described the properties of the supposed compound, e.g. it was said to be lighter than air, and heavier than hydrogen; to burn in air with a yellowish-white flame producing zinc oxide, and a small quantity of metallic zinc; and to explode when mixed with chlorine and ignited to produce zinc chloride and hydrogen chloride. It was further stated that it is not decomposed by nitric acid, or by easily reduced metallic salts. It is not absorbed by water, and does not combine with the bases. E. W. von Siemens and J. G. Halske, and A. R. Leeds believed in the existence of a gaseous zinc hydride; the latter regarded the blue colour of the flame of hydrogen obtained from zinc as evidence of the existence of a gaseous zinc hydride. R. L. Ruhland believed that he had obtained a solid zinc hydride by the electrolysis of zinc amalgam. C. A. Cameron denied that any gaseous zinc hydride is formed during the action of dil. acids on zinc, or the action of hydrogen sulphide on zinc amalgam. F. Paneth and co-workers observed no sign of the formation of zinc hydride by the action of activated hydrogen.

According to F. Fischer and G. Ilievici, the electric sparking of cadmium under liquid **argon** produces a voluminous olive-green powder, which forms cadmium oxide when calcined in air; the powder is insoluble in water, soluble in cold dil. hydrochloric, phosphoric, or acetic acid; and it is thought to be a nitride. According to O. Sackur, the catalytic activity of the following metals on the combustion of hydrogen decreases in the order Ag, Pt, Cu, Pb, Zn, Ni, Sn, Fe, Cr, and their proneness to assume the passive state increases in the same order.

P. A. von Bonsdorff² and M. Traube proved that zinc or cadmium remains bright in dry **oxygen**, or in dry **air** at ordinary temp., but if moisture be present, the hydroxide is formed, and if the air contains carbon dioxide as well, some basic carbonate is produced as a compact tenacious grey film which impedes the oxidation of the subjacent metal, and is thus unlike iron rust, which accelerates the oxidation of the subjacent metal. F. Stromeyer also stated that cadmium is tarnished by exposure to moist air, but if the air be free from carbon dioxide, the metal is not attacked. W. W. Coblenz found a polished cadmium plate was rendered matt by two days' exposure to air. When the surface of molten zinc is exposed to the air, it is speedily covered by a grey film, which is renewed as fast as it is removed, so that by repeated stirring the whole may be converted into a grey powder—*vide infra* zinc suboxide. According to J. F. Daniell, zinc takes fire in air at about 505°, and

it burns with a bluish-white flame, forming zinc oxide, *q.v.* O. Ohmann found zinc wool burns with a very brilliant flame when lighted with a Bunsen's burner. F. Stromeyer also noted that cadmium readily burns when heated in air, and W. Manchot detected the formation of some cadmium peroxide in the products of the reaction. J. Rothe and F. W. Hinrichsen found that moist air has no perceptible action on cast zinc after 6 hrs.' exposure, and a slight film appears after 8 hrs.' exposure. Moist air containing 5 per cent. of carbon dioxide, by vol., exerts no perceptible action in 6 hrs., but after 24 hrs. a white film is visible; the action is rather more pronounced if a greater proportion of carbon dioxide is present. If the air contains sulphur dioxide in place of carbon dioxide, the attack is faster, and it can be detected after half an hour's exposure of zinc to moist air with 5 vol. per cent. of sulphur dioxide. E. Jordis and W. Rosenhaupt observed that the action of oxygen on zinc begins about 180° ; and below 200° , moist oxygen acts more slowly, and above 200° more rapidly than the dried gas; at 300° the oxidation is twice as rapid with moist oxygen as it is with the dry gas, and the difference becomes less marked as the temp. rises. The effects are due not to the reaction itself, but rather to a kind of surface film which is developed. At a temp. below 150° , oxidation virtually ceases in dry oxygen as soon as the surface film is formed, while above 150° , the reaction continues. An oxidizable surface may be the result of (a) the soln. of oxygen in the metal; (b) the diffusion of the oxygen through the layer of oxide which may dissolve the oxygen or be merely porous to it; (c) the alternate formation of low and high oxides; or (d) the layer of oxide scaling off from the metal. P. Schwalbe studied the combustion of zinc in compressed oxygen and compressed air. N. B. Pilling and R. E. Bedworth found that at 400° , zinc oxidizes slowly in dry oxygen forming a milk-white film of oxide. G. Tammann and W. Köster studied the speed of formation of films on zinc and cadmium in heated air or oxygen.

Zinc dust can inflame in moist air owing to rapid oxidation. W. Manchot found that the temp. at which air and ozone act on zinc or cadmium are close together, but ozone acts more energetically. C. Engler and W. Wild found that clean and moist zinc filings react with ozone, forming a pale cloud of zinc oxide. G. C. Schmidt examined the action of canal rays on gases in the presence of zinc, etc. According to J. Priestley, A. von Humboldt, J. W. Ritter, W. Wilson, and J. C. L. Reinhold, zinc is more rapidly attacked if it be in contact with a piece of copper. M. Müller also noted that zinc tubes in contact with a copper roof were rapidly corroded. F. Mylius and R. Funk observed a peculiar corrosion of zinc anodes during the electrolysis of soln. of zinc sulphate; and J. H. Abernethy found that zinc is gradually dissolved from brass. According to P. A. von Bonsdorff, if two metals are placed, not in contact with one another, under a bell-jar containing air, and closed at the bottom with a water-seal, the more oxidizable metal is alone bedewed, and therefore oxidized; for example, arsenic or lead placed in a moist atm. near copper or silver. Again, if a piece of lead be placed under the receiver near a piece of zinc, the last-named metal remains bright while the lead is tarnished. The contrary effect is produced if the metals are in contact—thus, if copper is placed in contact with silver, the moisture condenses only on the surface of the last-named metal—*vide* sacrificial metals—1. 16, 3.

M. Pettenkofer and A. Bolzano studied the corrosive action of atm. air on zinc. The former found that a zinc roof in München oxidized 8.381 grms. per sq. ft. (Bavarian) in 27 years—the film of oxide was about 0.1 mm. thick, and had the composition $5\text{ZnO} \cdot 4\text{CO}_2 \cdot 8\text{H}_2\text{O}$. G. T. Moody suspended strips of thin sheet zinc in a muslin bag under the shelter of a north wall, and exposed to the full effects of the atm. for 5 months; the semi-crystalline scale which was formed had a composition agreeing closely with $\text{ZnCO}_3 \cdot 3\text{Zn}(\text{OH})_2$. G. T. Moody regards this as evidence that the atm. corrosion of zinc is not due to the direct oxidation of the metal, but to an interaction with carbonic acid. W. R. Dunstan regarded the atm. oxidation of zinc as a complex process in which,

as shown by M. Traube, W. Smith, and H. T. Barnes and G. W. Shearer, hydrogen peroxide is formed as an intermediate product— $\text{Zn} + \text{O}_2 + 2\text{H}_2\text{O} = \text{Zn}(\text{OH})_2 + \text{H}_2\text{O}_2$, followed by $\text{Zn} + \text{H}_2\text{O}_2 = \text{Zn}(\text{OH})_2$ —which can be detected during the process of oxidation. W. Merckens arranged the metals in the order: Mg, Al, Zn, Cd, Ni, Co, Pb, according to their power of forming hydrogen peroxide during their oxidation. Any reagent which prevents the formation of hydrogen peroxide prevents the oxidation of the zinc. Any carbonate which may be present in the rust is a secondary effect due to the action of carbon dioxide on the zinc hydroxide. G. T. Moody found that commercial **hydrogen peroxide** rapidly transforms zinc into the hydroxide while 30 per cent. hydrogen peroxide has scarcely any action on the metal. W. R. Hodgkinson and A. H. Coote noted that an ammoniacal soln. of hydrogen peroxide rapidly dissolves zinc.

According to J. J. Berzelius, and W. van Rijn, when zinc filings are moistened with **water** and exposed to the air, they acquire a dark colour, increase in vol., and hydrogen gas is evolved with a visible effervescence, while a grey oxide is formed. Zinc submerged in water in contact with air freed from carbon dioxide is soon covered by a film of oxide. F. Stromeier remarked that cadmium does not decompose water at ordinary temp.; and P. A. von Bonsdorff found that cadmium becomes covered with hydrated oxide when immersed in water exposed to air free from carbon dioxide, but if the latter gas be present, the deposit contains some carbonate. According to P. A. von Bonsdorff and P. H. Boutigny, zinc does not attack purified water at ordinary temp.; and the metal together with water, freed from air by boiling, may be sealed up in a glass tube and kept for a year without any diminution in the brightness of the metal. C. F. Schönbein showed that hydrogen peroxide is formed when zinc, cadmium, lead, or copper is in contact with water and air. M. T. Mengarini found that when in contact with distilled water, zinc gradually yielded a colloidal soln. of zinc or zinc oxide or hydroxide, which can be detected by the ultramicroscope. J. Davy stated that zinc does not decompose boiling purified water even if the zinc be in contact with copper, but if the water contains a salt in soln., reaction does occur. On the contrary, J. J. Berzelius, J. Thomsen, J. P. Cooke and W. Smith maintained that boiling water is decomposed by zinc; and J. Percy found that commercial sheet zinc is slowly decomposed by water just below 100° and from which air had previously been expelled by boiling; the evolution of hydrogen decreased after one or two hrs. The contradictions are due to inattention to the degree of purity of the zinc. L. l'Hôte showed that highly purified zinc does not give hydrogen when boiled for a long time with water, but if 0.03 to 0.05 per cent. of iron or a trace of arsenic or antimony is present, zinc does decompose boiling water. B. Roux also showed that the influence of water on zinc is dependent on the nature of the water. When the metal is boiled with water in glass vessels, the alkali dissolved from the glass was shown by H. E. Davies to have an important influence on the results. L. B. G. de Morveau noted that rain-water does not attack zinc while spring-water does so, and numerous cases have been reported—by C. W. Heaton, F. Schwarz, T. Stevenson, T. L. Phipson, H. Struve, P. A. E. Richards, P. F. Frankland, M. E. Chevreul, O. Krug and M. Rautert, H. Fleck, H. W. Bettink and J. van Eyk, A. Wagner, J. Nessler, A. Brüning, M. Ter-gast, E. Hylus, F. Hundeshagen, J. L. Howe and J. L. Morrison, C. H. Ehrenfeld, etc.—where water which has passed through zinc pipes, or galvanized iron pipes, or been stored in zinc-lined tanks, is contaminated with a soluble compound of zinc. H. E. Davies found that water which had passed through a considerable length of galvanized iron-pipe contained 1.7 parts of zinc per 100,000 parts of water; C. W. Heaton, 6.41 grains per gallon; and F. P. Venable, 4.48 grains per gallon. A. Smetham mentioned a boiler deposit with 44 per cent. of zinc oxide. According to A. Siersch, zinc dissolves rapidly in soln. of alkali chlorides and sulphates; O. Aschan found that sea-water attacks zinc more rapidly than purified water, and F. C. Calvert and R. Johnson found that in one month 100 litres of sea-water dissolved 5.66 grms. per sq. metre of zinc, or 1.12 grms. per sq. metre of galvanized iron.

A. J. C. Snyders reported that hard well waters do not act on zinc, but soft-waters and rain-water containing ammonium salts do act on that metal. The solubility of zinc in natural waters is said to depend on the proportion which exists between the carbonates and phosphates, and the chlorides, sulphates, and nitrates, the most injurious salts of the latter class being the ammonium salts, then the chlorides of the alkaline earths, and the chlorides and sulphates of the alkalis. A. J. C. Snyders further stated that zinc decomposes saline soln., whether conc. or dil. without access of oxygen, evolving hydrogen and forming zinc oxide. From his experiments on the action of water and saline soln. on zinc, X. Rocques concluded that zinc is attacked very slowly by ordinary water and saline soln. in general, *i.e.* containing chlorides and bi-carbonates. If several metals are present the action is much more rapid. The maximum effect occurs in presence of oxygen. This is particularly the case at the surface of the reservoir where the metal is in contact with air and water by turns. H. E. Davies concluded that all kinds of water attack zinc in the presence of air, and that rain-water exerts least action; a moderate degree of hardness favours the action, while extreme hardness does not prevent the action. When the metal is covered by a film of the hydroxide, the action does not cease, although its speed is much reduced. When water containing zinc compounds is drunk, zinc is afterwards found in all the viscera.

W. Smith, and X. Rocques noted that the presence of ammonia or nitrogenous organic matter in water accelerates the attack. O. P. Watts and N. D. Whipple studied the corrosion of cadmium, zinc, and zinc amalgam by hydrochloric, nitric, chromic, sulphuric, perchloric, phosphoric, and acetic acids; by sodium hydroxide soln.; and by soln. of hydrogen peroxide; sodium nitrite and arsenate; ferric sulphate and chloride; potassium chlorate, dichromate, permanganate, nitrate, bromide, and iodide; and by mercuric chloride. They added that amalgamation protects zinc from acids because the discharge potential of hydrogen on mercury exceeds that on zinc. A. J. Hale and H. S. Foster examined the action of nitric, sulphuric, and hydrochloric acids; aq. ammonia; sodium hydroxide, chloride, and carbonate; and magnesium and calcium chlorides on zinc. According to L. Santi, A. Bringhenti, A. Wagner, and A. J. C. Snyders, zinc also dissolves in a soln. of **ammonium chloride**. M. Müller found that the reaction is faster if air be present. According to H. Ritthausen, a dil. or conc. soln. of purified ammonium chloride is not perceptibly decomposed by zinc either at ordinary temp. or when warmed, but if some cupric chloride or an acid or alkali is present, the soln. is decomposed. A. Bringhenti found the reaction with a soln. of **ammonium fluoride** to be very vigorous. J. B. Davies, and J. E. Lorin, also showed that soln. of ammonium salts favour the dissolution of zinc. W. Smith, and A. J. Hale and H. S. Foster observed that a soln. of **sodium chloride** dissolves zinc, A. Siersch found that hydrogen is evolved, and a soln. of sodium zinc chloride and a deposit of zinc oxide formed. A. Krefting exposed a mixture of sodium chloride and zinc filings to moist air and obtained a mixture of zinc hydroxide with basic chloride and carbonate. C. H. Crowe studied the action of the chlorides, sulphates, and nitrates of potassium, sodium, and magnesium and found that while zinc was attacked by the nitrates and sulphates, it was scarcely affected by the chlorides. A. Vogel stated that when zinc or cadmium, under water containing $\frac{1}{300}$ th part of **potassium hydroxide**, is exposed to air, the metal turns grey, and forms shining laminae of zinc carbonate, but no zinc dissolves in the water. A. Langlois also studied this reaction. As shown by A. Langlois, A. J. Hale and H. S. Foster, A. Vogel, A. Destrem, L. de Boisbaudran, J. A. Poumarède, G. Bischof, and J. M. F. de Lassone, zinc dissolves slowly in soln. of the **alkali hydroxides** liberating hydrogen, and forming a soluble alkali zincate; the presence of the more electro-negative metals accelerates the process of dissolution, thus F. F. Runge found the speed of soln. is greater when the zinc is in contact with platinum, and still more so when in contact with iron. According to A. J. C. Snyders, the greater solvent action of saline water is due to the increased solubility of the zinc oxide in the liquid. Thus, C. Matignon and G. Desplantes stated that the oxidation of cadmium

or zinc by water in the presence of oxygen is not accelerated appreciably by ammonia, but that the presence of ammonia favours the reaction by dissolving the product of the oxidation. R. Ihle found that zinc is rapidly oxidized in aerated water or salt soln., and that the reaction is retarded by hydroxides, carbonates, phosphates, borates, and nitrites, but accelerated by chlorides, bromides, chlorates, nitrates, sulphates, etc. According to H. V. Regnault, when water vapour is passed over zinc at a dull red heat, hydrogen gas is liberated, and small crystals of oxide are deposited on the metal. H. St. C. Deville also studied the reaction: $\text{Zn} + 2\text{H}_2\text{O} \rightleftharpoons \text{Zn}(\text{OH})_2 + \text{H}_2$. H. V. Regnault found that cadmium acts in a similar manner.

Zinc unites energetically with most of the metalloids; and the properties of cadmium closely resemble those of zinc, but the chemical energy of cadmium is the smaller. For example, the thermal values of the reactions with zinc are usually greater than those with cadmium; and zinc will precipitate cadmium from soln. of its salts, and this property has been utilized in separating the two metals—*vide* cadmium. According to H. Moissan,³ **fluorine** reacts with warm powdered zinc with incandescence. According to H. Davy, zinc-foil at ordinary temp. inflames in **chlorine**; and T. Andrews stated that although zinc combines energetically with moist chlorine, “perfectly dry chlorine has no action whatever at ordinary temp., . . . and the same remark applies to the action of dry bromine in contact with the dry metals.” R. Cowper also found that neither the dry gas nor liquid chlorine attacks zinc or cadmium at ordinary temp. C. Löwig found that zinc does not combine with **bromine** even when the bromine is dropped on the heated metal, although J. B. Berthelot noted that the two elements react at a red heat. A. J. Balard found that zinc readily dissolves in bromine water; J. L. Gay Lussac found that **iodine** and zinc readily combine with the evolution of a small amount of heat. The heat of the reaction between the halogens and zinc is greater, the smaller the at. wt. of the halogen. A. Schükareff represented the speeds of the reactions between an aq. soln. and one of the halogens and zinc by the formula $\log (C/C') = kt$, where C and C' represent conc., and t the time. The quantities of halogen reacting during a given time in equally conc. soln. on equal surfaces of the metal are equal; or, in other words, the quantities of metal reacting in a given time at equal or equivalent conc. are proportional to the at. wt. of the metal, and inversely proportional to its valency in the compound formed. G. Tammann and W. Köster studied the formation of films on zinc exposed to chlorine or bromine mixed with air. G. Tammann studied the character of the film produced when zinc or cadmium is exposed to the vapour of iodine at ordinary temp.

The gaseous **hydrogen halides** and their aq. soln. readily attack zinc with the evolution of hydrogen, and the formation of the corresponding zinc halide. N. N. Beketoff⁴ found that when dry cadmium is heated in an atm. of dry hydrogen chloride at 440°, about 98 per cent. of the gas is decomposed: $\text{Cd} + 2\text{HCl} \rightleftharpoons \text{CdCl}_2 + \text{H}_2$. From the time of C. F. Wenzel's study of the kinetics of that class of heterogeneous reactions represented by the dissolution of zinc in various acids, in 1777, a great deal of the work has been done with this metal. The subject has been investigated by T. Ericson-Aurén and W. Palmaer, A. J. Hale and H. S. Foster, E. Brunner, etc. These reactions are more sensitive to disturbing influences than those which take place in homogeneous systems. As shown by F. C. Calvert and R. Johnson, the speed of the reaction is influenced by variations in the rugosity of the surface of the dissolving metal: they stated that

Cubes, which had been made of the same zinc but at different times, were acted upon more or less by the same acid when placed under the same circumstances; and these observations gradually led us to the discovery of a curious fact, viz., that a perfectly clean surface of zinc will become after a few days sufficiently oxidized by contact with air to modify in a very marked degree the action of sulphuric acid upon it. Thus, if a cube of zinc recently filed is placed in sulphuric acid diluted with nine equivalents of water, the action may be considered as nil; whilst if the same cube be gently heated in contact with air and allowed to cool, and be then placed in the same strength of acid, the attack is marked.

Hence, the roughness of the surface and not oxidation is the *vera causa* of the increased velocity, for superficial oxidation could not exert more than a momentary influence owing to the solubility of the oxide in the acid. The speed of the action is also modified by the local rise of temp. due to chemical action, by the rate of diffusion of the products of the reaction in the acid liquid; by the disengagement of gas-bubbles from the surface of the metal; by the impurities associated with the metal; and, as shown by G. Tammann, W. Nernst, and F. Kunschert, E. Brunner, etc., by the difference of potential between the metal and the acid; and by the conductivity of the soln. K. Jablczynsky concluded that the velocity of dissolution of a solid with a perfectly smooth surface increases proportionally with the *velocity of stirring*, and if the surface of the solid is not smooth, the increase of the velocity constant is slower than the increase of the velocity of stirring, and the more so the rougher the surface. H. J. Prins found the rate of dissolution of zinc in many acids is accelerated by the presence of nitrobenzene, or benzaldehyde; and A. Sieverts and P. Lueg, that the presence of a trace of nicotine, quinine, or of α - or β -naphthoquinoline greatly retarded the activity of hydrochloric acid.

Highly purified zinc was shown by A. A. de la Rive to be scarcely affected by the acid. The most rapid action occurred when commercial zinc was treated with about 30 per cent. sulphuric acid. He added known quantities of tin, lead, copper, and iron, respectively, to molten redistilled zinc, and found that the rates of action of the products with sulphuric acid soln. were greater than the rate of action of redistilled zinc. Finally, he proved that the soln. of sulphuric acid which showed maximum electrical conductivity interacted most rapidly with commercial zinc, and with redistilled zinc to which a few per cent. of iron had been added. He concluded that the interaction between pure zinc and dil. sulphuric acid is probably a direct chemical change, but that with ordinary commercial zinc the action is chiefly electrochemical. M. Faraday also proved that a plate of amalgamated zinc remained unchanged in sulphuric acid, to which 30 parts of water had been added, while a similar plate in the same acid, and in contact with a platinum plate, was rapidly dissolved. N. A. E. Millon added that the more pure the zinc, the slower the action of the acid, but the purified metal readily dissolves if it be in contact with platinum or some other electronegative metal. In illustration, with $\frac{1}{10}$ -normal hydrochloric acid 39 c.c. of gas were evolved by the dissolution of zinc for 300 minutes under conditions where 78 c.c. were evolved when the zinc was in contact with platinum. In 600 minutes the numbers were respectively 68.4 c.c. and 103.3 c.c. H. C. Reynolds and W. Ramsay found highly purified zinc to be nearly unacted upon by hydrochloric or sulphuric acid. Hence, the reaction between zinc and dil. sulphuric acid is probably electrolytic, and dependent on the formation of local galvanic couples on the surface of the dissolving metal. It has therefore been inferred that pure zinc is insoluble in pure acid, and that if a third substance be present in metal or acid, dissolution takes place by the formation of an electrical circuit. Purified cadmium behaves similarly. The *reversed electrolysis* theory of chemical action developed by H. E. Armstrong assumes that two substances will react only in the presence of certain impurities; pure substances do not interact. Before chemical action can occur, a conducting system must be established between the two interacting substances and the third component. J. M. Weeren believed that the resistance offered by purified cadmium or zinc to the acid is due to the immediate formation of a film of hydrogen which shields the metal from the acid. J. C. d'Almeida, and F. Pallinger observed that the hydrogen is liberated from the impurities in metallic zinc when the acid has free access to the metal. A. Coehn and W. Caspari stated that the resistance which purified zinc offers to attack by acids depends on the high overvoltage of hydrogen and zinc, which is lowered from 0.70 volt to 0.23 volt when the zinc is in contact with copper, and to 0.15 volt when the zinc is in contact with silver, and the zinc then readily dissolves. C. Düsing also found zinc with 3–15 per cent. of iron is very resistant, and this alloy has therefore been recommended as anode in the electrolysis of soln.

of zinc salts. F. Novak found that by raising the proportion of cadmium in plumbiferous zinc, the velocity of attack is reduced, and the period of induction is extended.

W. Spring and E. van Aubel measured the speed of dissolution of zinc in sulphuric acid, **hydrochloric acid**, **hydrobromic acid**, and **hydriodic acid**. They found that the rate of dissolution is proportional to the conc. of the acid. F. Zecchini also found that the velocity of the reaction is approximately the same with $\frac{1}{10}N$ -soln. of hydrochloric and sulphuric acids at ordinary temp., and that the speed of attack increases proportionally with the conc. of the acid but faster with hydrochloric than with sulphuric acid. E. Divers and T. Shimidzu concluded from their observations on the rate of dissolution of zinc in sulphuric and nitric acids that other circumstances being equal the time taken to neutralize a given quantity of acid, or to complete some other chemical action upon it, is directly proportional to the dilution of the acid, and inversely as the area of contact between the metal and the soln. It is independent of the quantity of the acid. W. Ostwald observed that the relative affinity of hydrochloric and sulphuric acids on zinc, increases as the conc. decreases. According to W. Spring and E. van Aubel, the effect of *temperature* on the speed of dissolution of zinc in hydrochloric acid is shown by a curve asymptotic to the temp. axis, and that the isothermal curves for 5, 10, and 15 per cent. hydrochloric acid, at 15°, 35°, and 55°, all converge to zero, corresponding with -60° to -70°. T. Ericson-Aurén found that with very dil. acids, the speed of dissolution is scarcely affected by the temp. F. Zecchini found the effect of temp. is less with hydrochloric acid than with sulphuric acid; a rise from 10° to 50° raises the velocity with 0.1 to 0.5N-H₂SO₄ by 50 to 150 per cent. L. P. Caillaudet, M. Berthelot, J. Babinet and P. A. Favre, and J. W. Gunning noted the decrease in the solubility of zinc in acids under *pressure*—*vide* 1. 7, 5. W. Hankel studied the *electrical phenomena* associated with the action of acids on zinc; and G. Berndt found that the rate of dissolution of zinc in hydrochloric acid is not influenced by a *magnetic field*. Owing to differences in the crystalline structure of the metal, rolled zinc is more readily attacked by dil. acids than is cast zinc, and P. A. Bolley maintained that zinc cast at a low temp. is much more rapidly attacked by acids than when the metal is cast at a red heat. The subject has been investigated by M. Barrett, K. Begemann, and C. F. Rammelsberg.

E. J. Mills and W. J. Mackey noted the *period of induction* in the dissolution of metals in acids—*vide* 1. 7, 4. M. Centnerszwer assumed that the period of induction with zinc is due to the metal passing from a passive to an active state—*vide* passive zinc. W. Spring and E. van Aubel divided the reaction into three stages: The first is a period of induction which they suppose to be abnormal, and is dependent on the production of an indefinitely large number of minute galvanic couples on the surface of the metal; in the second stage the activity attains its maximum value; and in the third stage, this activity decreases as the conc. of the acid is diminished. A. J. J. van de Velde found that for all conc. of hydrochloric acid, the period of induction with hydrochloric acid is longer than with sulphuric acid, and with the latter it is longer than with nitric acid; he also found that the period of induction is abbreviated in the presence of cupric salts; and that the activity of the acid is proportional to the conc. of the hydrogen ions. A. Merget showed that zinc on which any metal of the last three groups of Mendeléeff's table has been deposited is attacked by nitric acid only on the uncovered portions, while, on the contrary, sulphuric, hydrochloric, or acetic acid attacks only the covered portions. C. Gourdon found that zinc partly covered with a thin layer of precipitated platinum is attacked and dissolved by sulphuric acid dil. with 7000 times its vol. of water. With gold it is attacked by an acid dil. with 5000 parts of water; copper requires an acid dil. with 4000 vols., silver 3500 vols., tin 1500 vols., antimony 700 vols., bismuth 500 vols., and lead 400 vols. The action is irregular with mercury, the spot gradually enlarging, and the zinc being dissolved only at the edges of the spot. The arsenites, arsenates, and antimonates also give spots which promote the soln. of the zinc, but the action is less

energetic. Deposits of cobalt, nickel, and iron, on the contrary, are comparable with those of platinum in their action, indeed cobalt causes the dissolution of the zinc by sulphuric acid dil. with 10,000 times its vol. of water. Salts of the same base, but with different acids, yield deposits which do not behave in the same way, the chlorides giving deposits which are more active than those produced by the sulphates, which in their turn excel those of the corresponding nitrates. Moreover, salts rendered slightly alkaline by the addition of ammonia give a more active deposit than the salts themselves; ferrous sulphate, for instance, produced no deposit by itself, but on adding ammonia a very active one is formed. Zinc thus covered with a metallic deposit is also readily attacked by alkalis.

According to F. Zecchini, the addition of zinc sulphate lowers the rate of the attack on zinc by sulphuric acid, and the addition of zinc chloride to hydrochloric acid at first decreases and then increases the speed of attack. J. Ball studied the effect of soluble sulphates on the speed of attack by sulphuric acid, and of soluble chlorides on the speed of attack by hydrochloric acid. The relative maximum velocities with sulphates and sulphuric acid with the velocity without any addition, taken as unity, are:

	Mg	A	Cr	Mn	Fe	Ag	Co	Cu	Ni
Sulphates . . .	0.98	1.02	1.66	2.06	2.34	9.36	18.09	21.7	37.87

Here, the effects with the first two are within the limits of experimental error, and these salts may be regarded as having no influence. The other salts accelerate the attack. Similarly with chlorides and hydrochloric acid:

	Mn	Pb	Sn	Cu	Co	Au	Pt	Ni
Chlorides . . .	1.62	3.15	5.07	10.96	30.68	38.90	42.19	45.48

This subject has also been studied by F. Selmi, who found that the reaction between zinc and sulphuric acid is accelerated by small additions of manganese, magnesium, or iron sulphate, but not much affected by alkali or aluminium sulphate. G. Lunge observed that the activity of hydrochloric or sulphuric acid is lessened by admixture with gum, glycerol, or lampblack. F. Zecchini found that a soln. of hydrogen chloride in methyl, ethyl, or amyl alcohol, in acetone, or in aq. acetone attacks zinc, and the action of the ethereal soln., is most vigorous in spite of the insignificant ionization of the acid in soln. L. Kahlenberg, and H. E. Patten have studied the action of soln. of hydrogen chloride in benzene, and found a slow reaction which is accelerated by the addition of a little water. W. G. Falk and C. E. Waters found that a zinc rod wound with platinum is attacked by a soln. of hydrogen chloride in benzene, more slowly than a rod of purified zinc. H. E. Patten found the metal—zinc or cadmium—is only slightly attacked by a soln. of hydrogen chloride in chloroform, or arsenic trichloride, or carbon tetrachloride; but a marked corrosion occurs in benzene soln. L. Kahlenberg and H. Schlundt found a soln. of hydrogen chloride in liquid hydrogen cyanide attacks zinc.

The action of zinc on soln. of various **chlorides** has been already discussed. B. D. Steele found that when a soln. of **potassium iodide** is electrolyzed with a zinc anode, iodine is not set free, and the soln. becomes yellow, probably owing to the formation of zinc iodide. F. von Lerch studied the action of zinc on a hydrochloric acid soln. of **thorium X**. A. Terrell found zinc reacts explosively when heated with **manganese chloride**; R. Lorenz said that cadmium dissolves in molten **cadmium chloride**; N. N. Beketoff reported that a stream of hydrogen and zinc vapour attacks **barium chloride** superficially; O. Ruff, F. Eisner, and W. Heller found zinc rapidly attacks **tungsten hexafluoride**, especially if it contains some hydrogen fluoride, and hot or moist **tungsten oxytetrafluoride**, WOF_4 , is also attacked; further, O. Ruff and H. Graf noted that heated **arsenic pentafluoride** acts on zinc, forming arsenic and zinc fluoride. J. H. Gladstone and A. Tribe found that zinc decomposes water in the presence of **aluminium iodide**.

According to A. D. White,⁵ cadmium is not attacked by an aq. soln. of **bleaching powder**, and zinc is acted on only to a slight extent "because of the presence of

arsenic"; H. P. Pearson also found a very slight action at first, but at the end of a fortnight some zinc oxide was formed, which increased to a powdery deposit at the end of six months. W. S. Hendrixson studied the action of zinc and cadmium on **chloric acid** (*q.v.*). A. L. Voegelé found that zinc cathodes favoured the electrolytic reduction of **potassium chlorate**; and K. Weger found that in sulphuric or acetic acid soln. of chlorates a film of a basic salt is formed on the electrode, and this acts like a porous diaphragm. A. F. de Fourcroy and L. N. Vauquelin found that a mixture of powdered zinc and an oxidizing agent like potassium chlorate, detonates by percussion. G. Pellagri found that zinc powder reduces **potassium iodate** incompletely; the reaction is complete with a zinc-copper couple.

Zinc has a strong affinity for **sulphur**, and W. Spring,⁶ and L. Franck found that under a press. of 6500 atm. cadmium or zinc and sulphur unite to form the sulphide. C. Friedel, and E. Jannettaz question Spring's conclusion—*vide* 1. 14, 18. E. Schwarz showed that the reaction between sulphur and a mass of the metal proceeds with difficulty because a protective layer of sulphide is formed; on the other hand, a mixture of powdered zinc and sulphur reacts with explosive violence when warmed. The reaction between zinc and **selenium** or **tellurium** is accompanied by incandescence. Cadmium behaves similarly, but the reaction is not so vigorous. Zinc is attacked by **hydrogen sulphide** at ordinary temp., and a layer of sulphide is formed which protects the metal from further attack; when heated in a stream of hydrogen sulphide the attack is vigorous. G. Tammann and W. Köster studied the formation of films on zinc and cadmium exposed to hydrogen sulphide. R. Lorenz prepared crystals of wurtzite in this way. E. Schwarz found **carbon disulphide** is reduced by powdered zinc, forming, with incandescence, zinc sulphide and carbon. P. Nicolardot found that zinc and cadmium are only slightly attacked by **sulphur chloride**, S_2Cl_2 , and only after a prolonged action at as high a temp. as possible; F. Wöhler also noted the slow attack of zinc by sulphur chloride. E. Fromm found that a soln. of **sulphuryl chloride**, SO_2Cl_2 , in absolute ether, forms zinc chloride, sulphur dioxide, or zinc hyposulphite. P. Schutzenberger found that zinc dissolves without the evolution of gas in an aq. soln. of **sulphur dioxide**, forming zinc hyposulphite, ZnS_2O_4 ; and A. Nabl obtained a similar product by using an alcoholic soln. P. Schweitzer found that with cadmium and sulphurous acid, the liquid first becomes yellow, then clear, then dark, and sulphur and cadmium sulphide are precipitated; when the mixture is boiled in the presence of hydrochloric acid, cadmium sulphide is precipitated at once. Among the products of the reaction, after a sufficiently long period, were cadmium sulphate, sulphite, thiosulphate, trithionate, and sulphide. After filtration and washing the precipitate contained only cadmium sulphide. Similar products were obtained with zinc. M. Berthelot also studied the action of sulphurous acid on cadmium, and found that in the presence of sulphuric or hydrochloric acid, cadmium sulphide and sulphur are formed; C. Geitner found that under press., zinc and an aq. soln. of sulphur dioxide form zinc sulphate and sulphide, and free sulphur. J. Uhl also noted the formation of a sulphide as well as sulphate and sulphite when zinc or cadmium is heated in a stream of sulphur dioxide. M. Prud'homme found that with a soln. of **ammonium sulphite**, zinc forms zinc diammino-sulphate and ammonium hyposulphite. The corresponding reaction with **sodium sulphite**, and with **sodium hydrosulphite**, has been studied by R. von Wagner, and E. Berglund. F. Faktor said that cadmium colours yellow a boiling soln. of **sodium thiosulphate**.

The action of zinc and cadmium on **sulphuric acid** has been discussed generally in connection with its action on hydrochloric acid. The metal readily dissolves in dil. sulphuric acid, but, as shown by W. R. Grove,⁷ and J. C. d'Almeida, amalgamated zinc is not attacked by this acid. P. B. Ganguly and B. C. Banerji found that rods of cadmium or zinc, partially immersed in the dil. acid, are most vigorously attacked near the surface of the liquid. A. Ditte found that at a low temp., dil. sulphuric acid and zinc furnish hydrogen and hydrogen sulphide, and some sulphur (soluble in carbon disulphide); at a higher temp. and with conc. acid, some sulphur

dioxide is formed. M. Berthelot found that 0.5 grm. of cadmium with 2 c.c. of sulphuric acid in a sealed tube at ordinary temp. developed 0.2 c.c. of hydrogen at ordinary temp., and at 100°, 3.5 grms., cadmium sulphate were also produced. At 160°, no hydrogen is formed, but only sulphur dioxide, and this the more the higher the temp. of the reaction. According to M. M. P. Muir and C. E. Robbs, conc. sulphuric acid, $7\text{H}_2\text{SO}_4 + 2\text{H}_2\text{O}$, exerts no action on zinc until a high temp. is reached, and that the gaseous product of the action which then occurs is sulphur dioxide, accompanied by separation of a little sulphur; $7\text{H}_2\text{SO}_4, 4\text{H}_2\text{O}$ acts in a similar manner, but more sulphur separates; with $7\text{H}_2\text{SO}_4, 6\text{H}_2\text{O}$, sulphur is no longer produced, but only hydrogen sulphide; as the acid is made more dil., the action commences at lower temp. with evolution of hydrogen and traces of hydrogen sulphide, or of hydrogen alone; the quantity of hydrogen sulphide is increased by rise of temp., but it is not accompanied by sulphur dioxide or sulphur. M. M. P. Muir and R. H. Adie added further that the dependence of the production of hydrogen sulphide and sulphur dioxide on the temp. and conc. of the acid indicates that the formation of these gases is not to be ascribed to the reducing action of nascent hydrogen on the acid. This is confirmed by the observation that variations in the mass of zinc employed and the quantity of hydrogen produced in a given time, do not exert any marked or regular effect on the nature of the change; and further confirmed by the observations that an acid of conc. $\text{H}_2\text{SO}_4 + 2\text{H}_2\text{O}$ with commercial zinc gives very little sulphur dioxide or hydrogen sulphide at 100°, while both gases are produced freely at 165°, and a large proportion of hydrogen sulphide at 180°; with purified zinc both gases are produced at 165°. If the gases were secondary products of the reduction of sulphuric acid by the hydrogen evolved in the primary change, it might be expected that both gases would be formed as freely with purified as with commercial zinc. It is probable that the interaction between approximately pure zinc and acid is chiefly a direct chemical interaction, and that the products of the reactions with less pure zinc are largely due to the occurrence of secondary electrolytic changes. With pure, or almost pure, zinc and dil. acid (say $\text{H}_2\text{SO}_4.12$ to $15\text{H}_2\text{O}$), hydrogen and zinc sulphate are the only products of the reaction; with the same zinc and conc. acids (say $\text{H}_2\text{SO}_4.\text{H}_2\text{O}$ to H_2SO_4) the chief gaseous product is sulphur dioxide; and hydrogen sulphide is also produced at higher temp.; with sulphuric acid of intermediate conc. (say $\text{H}_2\text{SO}_4.2\text{H}_2\text{O}$) both compounds of sulphur are formed in considerable quantities at fairly high temp., *viz.* 160°.

The higher the degree of purity of the zinc, the smaller the proportion of sulphur dioxide to that of hydrogen sulphide at ordinary temp. whether the acid be dil. or conc. With an acid more dil. than $\text{H}_2\text{SO}_4 + 10\text{H}_2\text{O}$, hydrogen is almost the sole gaseous product even at temp. up to the b.p. of the acid. With purified zinc, at about 160°, the dil. of the acid is accompanied by a decrease in the proportion of sulphur dioxide and hydrogen sulphide produced, but with commercial zinc, the sulphur dioxide diminishes more than the hydrogen sulphide. The latter gas is always found with commercial zinc at dilutions down to $\text{H}_2\text{SO}_4 + 100\text{H}_2\text{O}$, and at temp. from 0° to the b.p. of the acid. Platinized zinc behaves very like commercial zinc. Sulphur is produced neither at low temp. nor with acids less conc. than $\text{H}_2\text{SO}_4 + 2\text{H}_2\text{O}$, and when sulphur is produced, sulphur dioxide and hydrogen sulphide are always formed. With purified zinc and sulphuric acid, there is scarcely any separation of sulphur; with platinized foil, on the other hand, sulphur is formed in large quantities. The sulphur can scarcely be a product of the interaction of sulphur dioxide and hydrogen sulphide, else it might be expected to generally accompany these gases; nor can it always be produced by the reducing action of the nascent hydrogen on either the sulphur dioxide or hydrogen sulphide, because these gases are so frequently found at moderate temp. unaccompanied by sulphur. The formation of sulphur can sometimes be traced to the mutual action of hydrogen sulphide and hot conc. sulphuric acid. This supposition would account for the preponderance of sulphur dioxide over hydrogen sulphide when the acid is

conc. and for the increase in the quantity of the latter gas as the acid becomes more dil.; for the hydrogen sulphide supposed to be formed when the acid is conc. would be decomposed by reacting with the hot acid, but would escape unchanged when the acid becomes more dil. The fact that the cessation in the production of sulphur is accompanied by a marked increase in the quantity of sulphuretted hydrogen in the reaction of platinized foil with conc. acids, is also in keeping with this supposition.

W. B. Hart, A. J. Hale and H. S. Foster, A. Sieverts and P. Lueg, and E. Brunner have also studied the reaction between zinc and sulphuric acid; and E. J. Mills and W. M. D. Mackey obtained a formula showing the effect of the conc. of the acid on the process. M. Barrett studied the state of aggregation of the zinc on the rate of dissolution in dil. sulphuric acid. F. Pullinger found that zinc with a perfectly smooth surface is not acted upon by dil. sulphuric acid which has been submitted to prolonged boiling. That pure zinc with a rough surface is readily acted upon, but in a less degree by acids which have been boiled than by those which have not. That oxidizing agents, such as electrolyzed sulphuric acid, hydrogen peroxide, and nitric acid, increase the rate of dissolution. That a reducing agent, such as hydriodic acid, almost entirely prevents dissolution, but that those containing sulphur, such as sulphur dioxide, are without effect. That, in all probability, *pure* dil. sulphuric acid would, at ordinary temp., be entirely without action upon metallic zinc, whether the surface of the latter were rough or smooth. F. Pullinger assumed that ordinary "pure" sulphuric acid probably contains a small quantity of some substance which is wholly or partly decomposed or driven off by boiling. This substance is not hydrogen sulphide nor sulphur dioxide, and it is not hyposulphurous acid, nor any of the acids contained in Wackenroder's soln. From the fact that oxidizing agents, such as hydrogen peroxide, nitric acid, and sulphuric acid which has been electrolyzed increase the velocity of dissolution, it is not improbable that the third substance is some lightly oxygenated compound. This view is borne out by the action of hydriodic acid, a reducing agent which very greatly retards the rate of dissolution of zinc. He assumed that this third substance is persulphuric acid which acts as a catalytic agent in the reaction between zinc and sulphuric acid, analogous with nitrous acid in the reaction between copper and nitric acid (*q.v.*).

L. Kahlenberg and H. Schlundt found that zinc is not attacked by a soln. of **sulphur trioxide** in liquid hydrogen cyanide, but that it is attacked by a soln. of **fuming sulphuric acid** in that menstruum. Zinc decomposes **selenic acid**, H_2SeO_4 , and **molybdic acid**, H_2MoO_4 . The action of soln. of **alkali sulphates**, **magnesium sulphate**, and of **ammonium sulphate** on zinc has been investigated by A. Brighenti, A. J. C. Snyders, A. Wagner, and A. Krefting; the latter also studied the action of **sodium tungstate**. H. S. Rawdon and co-workers found the corrosion of annealed zinc by soln. of **zinc sulphate** is of an intercrystalline nature. A. R. Wahl studied the reduction of a soln. of **ferrie sulphate** to ferrous sulphate by zinc; he did not detect the evolution of any hydrogen, and utilized the reaction for the evaluation of zinc dust. S. Sugden also made observations on this reaction. F. Muck claimed that with a conc. soln. of **ferrous sulphate**, hydrogen is evolved, and an ochre-yellow deposit is formed. J. Löwe found that granulated zinc is slowly attacked by an aq. soln. of **alum**, and more vigorously when the zinc is in contact with platinum. R. Namias found zinc dissolves completely in neutral soln. of the **persulphates**—according to M. G. Levi and co-workers, with potassium persulphate the action with zinc or cadmium is rapid, with ammonium persulphate it is slower, and, as also shown by J. W. Turrentine, no gas is evolved. According to H. Ditz, a 10 per cent. soln. of ammonium persulphate in sulphuric acid gives off ozonized oxygen.

L. Arons⁸ observed that zinc nitride is probably formed in the electric arc between zinc electrodes in **nitrogen**, and appears as a fine deposit on the metal. F. H. Newman also studied the effect of nitrogen on zinc and cadmium as cathodes

in a discharge tube. W. Smith found that when zinc oxidizes in the presence of nitrogen; ammonia, ammonium nitrite and nitrate are formed; and in the spontaneous oxidization of zinc in air, nitrites and nitrates are sometimes produced. W. Smith observed that a hot, nearly boiling soln. of **ammonia** readily acts on zinc cuttings, and still more so on zinc filings; in both cases hydrogen is evolved, and a film of oxide formed which can be readily detached from the metal. W. R. Hodgkinson and N. E. Bellairs also found that zinc dissolves in aq. ammonia while exposed to air, but they did not observe the formation of any nitrite. S. Kappel showed that when the metal is left in contact with air and aq. ammonia, nitrites are formed. According to C. Matignon and G. Desplantes, the oxidation of zinc is not perceptibly augmented by aq. ammonia, the favourable result is a physical effect due to the solvent action of the aq. ammonia on the zinc oxide keeping the surface of the metal clean. G. T. Beilby and G. G. Henderson found that when zinc or brass is heated below its m.p., in a stream of ammonia, there are physical changes in the structure of the metal, and the ammonia is decomposed. A. H. White and L. Kirschbraun obtained a product containing zinc nitride by passing ammonia gas over zinc heated to about 600°. The temp. of decomposition and formation of zinc nitride are so close together that the product is always a mixture of the nitride and the metal. G. G. Henderson and J. C. Galletly showed that cadmium behaves in a similar manner, but a rather smaller proportion is converted into a greenish nitride. W. Weyl found liquid ammonia does not act on zinc, but when sodium-ammonium acts on zinc, sodium diammino-oxide, **zinc diammine**, $\text{Zn}(\text{NH}_3)_2$, are formed: $2\text{Na}(\text{NH}_3) + \text{Zn}(\text{NH}_3)_2\text{O} = \text{Zn}(\text{NH}_3)_2 + (\text{NH}_3\text{Na})_2\text{O}$. He said: silver chloride is sat. with ammonia in one leg of a **W**-tube, an eq. amount of zinc oxide with sodium is placed in the other leg—both legs are then sealed. The silver chloride part is placed in a calcium chloride bath, and the ammonia which is given off is absorbed by the zinc oxide in the other limb. The product is then allowed to act on sodium-ammonium. A deep blue liquid is formed which readily decomposes at 12°–15°. The action of aq. soln. of many **ammonium salts** on zinc is discussed both above and below. T. Curtius and A. Darapsky found that **azoimide** reacts with zinc with the evolution of hydrogen. P. Sabatier and J. B. Senderens found that zinc or cadmium is superficially oxidized by **nitric oxide**, and the metal is oxidized by **nitrogen peroxide** at 300°. The surface of molten zinc becomes matt in an atm. of nitric oxide, and by the action of **nitrous oxide** zinc oxide and nitrogen are formed. F. Emich obtained zinc oxide mixed with a little nitride by passing red-hot nitric oxide over zinc dust. W. R. Hodgkinson and A. H. Coote⁹ found that molten **ammonium nitrite** has less action on zinc than it has on cadmium or magnesium, and more than it has on copper, nickel, lead, or bismuth; ammonia is first given off, and the metal nitrate is formed; the nitrate is reduced to nitrite by the hydrogen; the nitrite reacts with the ammonia, and nitrogen is evolved—a gram-atom of cadmium produces a little less than 4 gram-atoms of nitrogen. J. J. Sudborough found **nitrosyl chloride** reacts only slightly with cadmium after many days' exposure at 100°.

When conc. **nitric acid** is poured on melted zinc, the metal becomes incandescent. P. T. Austen said that zinc does not burn in the vapour of nitric acid. N. A. E. Millon found that mono- or di-hydrated nitric acid, free from nitrous acid does not dissolve zinc at –18°, but the metal becomes covered with a yellowish-white film, which prevents further action; as the temp. rises a little above –18°, the film dissolves, and a vigorous action sets in. Zinc retains its metallic lustre in the tetrahydrated acid, and remains unaltered at –18°, but is violently attacked at 0°; a still more dil. acid reacts on zinc even at –18°. H. Braconnot found that conc. nitric acid dissolves zinc less readily than the more dil. acid because of the lower solubility of the product of the reaction in the conc. acid; and an alcoholic soln. of nitric acid acts very slowly with zinc because of the low solubility of zinc nitrate in that menstruum. F. Kuhlmann found that zinc reduces nitric acid forming some ammonia; A. M. Pleischl observed that some nitrous oxide is formed

when nitric acid reacts with zinc, and as the liquid gets hot, an increasing proportion of nitric oxide is formed. H. St. C. Deville showed that the products of the reaction include nitrous acid, nitrous oxide, nitric oxide, ammonia, and a little nitrogen; and, as shown by A. Terreil, E. Divers, and others, free hydrogen never appears as a product of the reaction between zinc and nitric acid. In an attempt to disprove the theory of *l'état naissant*, H. St. C. Deville studied the action of nitric acid of different conc., and of mixtures of nitric acid with sulphuric or hydrochloric acid, and measured the quantities of the acid consumed; he then concluded that each acid pursues its action on the zinc unaffected, except indirectly, by the presence of the other. J. J. Acworth and H. E. Armstrong concluded that in the action of nitric acid on zinc in vacuo, the gaseous product is a mixture of nitrogen and of nitrous and nitric oxides. J. J. Acworth found that in the presence of ammonium nitrate, the gaseous product is mainly nitrogen. A. Bertels stated that when an excess of nitric acid acts on zinc, a basic zinc nitrate is formed.

C. Montemartini made an extensive study of the action of nitric acid on zinc; he showed that the velocity of the dissolution of the zinc in nitric acid increases regularly with the conc. of the acid below 25 per cent.; it then falls slightly, remains constant between 33 per cent. and 42 per cent., then diminishes regularly, attaining its minimum value at a conc. of 68 per cent.; a considerable rise then takes place with increased conc., but the previous maximum value is not again attained. The products formed in the reaction at a low temp. when the acid is in large excess are nitrous acid, hyponitrous acid, nitric oxide, nitric peroxide, nitrous oxide, nitrogen, and ammonia. Under the conditions mentioned, hydroxylamine is not found among the final products of the reaction, and free hydrogen is never evolved. With the exception of nitrous acid and nitric peroxide, the above products are formed, whatever the degree of conc. of the acid; no nitrous acid is, however, formed if the soln. contains more than 30 per cent. of nitric acid, and no nitric peroxide if it contains less. At a temp. of 3°–8°, the quantity of *ammonia* in soln. rises rapidly until the conc. of the acid is 10 per cent., then slowly until a maximum is attained between 40 and 45 per cent.; it falls abruptly at 47 per cent., and at 53 per cent. only a very small quantity is produced, which gradually diminishes with increased conc., and may be represented by a straight line passing through the zero point at 100 per cent. At a temp. of 85°, the maximum occurs at a conc. of 9 per cent., when it is equal to the production at the lower temp.; it then falls rapidly as the conc. is increased to 15 per cent.; beyond this point it may be represented by a line passing through the zero point when the conc. is 100 per cent. At a temp. of 18°–21°, the production of *nitrous acid* increases rapidly with the temp. until a conc. of 14 per cent. of nitric acid is attained; it then falls with equal rapidity with increase of conc. to 30 per cent., at which stage nitrous acid ceases to appear among the final products. Between 18° and 22°, *nitrogen peroxide* is first formed at a conc. of 27 per cent. of acid; it increases slowly at first, rapidly between 64 per cent. and 72 per cent.; beyond 80 per cent. it remains almost constant. The formation of *nitrous oxide* takes place in comparatively large quantities and with great regularity. It reaches a maximum at a conc. of 40 per cent. acid and a minimum at 80 per cent. Nitrogen is formed only in very small quantities in acid of all degrees of conc. Similar results were obtained with cadmium, one gram of which in an excess of 27.5 per cent. nitric acid gave 0.00197 grm. of HN_3 ; 0.00695 grm. HNO_2 ; 0.00570 grm. N_2O ; 0.00033 grm. N_2 ; and 0.00216 grm. of NO . J. J. Acworth and H. E. Armstrong obtained more nitric oxide and less nitrous oxide and nitrogen with cadmium than with zinc—*vide* action of nitric acid on magnesium. A mixture of one part of sulphuric acid with 80 parts of water was found by J. M. H. Bignon to dissolve more zinc than when one part of nitric acid is also present, and J. W. Döbereiner explained the effect by assuming that in the latter case ammonia is formed which neutralizes some of the acid.

E. Divers showed that zinc is very effective in converting nitric acid into *hydroxylamine*, and ammonia is always produced at the same time. He assumes that zinc,

like tin, acts directly upon nitric acid, producing the metal nitrate, and independently, as primary products, ammonia, $4\text{Zn} + 9\text{HNO}_3 = 4\text{Zn}(\text{NO}_3)_2 + 3\text{H}_2\text{O} + \text{NH}_3$; nitrous oxide, $4\text{Zn} + 10\text{HNO}_3 = 4\text{Zn}(\text{NO}_3)_2 + 5\text{H}_2\text{O} + \text{N}_2\text{O}$; and nitrogen, $5\text{Zn} + 12\text{HNO}_3 = 5\text{Zn}(\text{NO}_3)_2 + 6\text{H}_2\text{O} + \text{N}_2$. The hydroxylamine also is produced as a primary product when sulphuric or hydrochloric acid is present to form a more stable product: $6\text{Zn} + 7\text{H}_2\text{SO}_4 + 2\text{HNO}_3 = 6\text{ZnSO}_4 + 4\text{H}_2\text{O} + (\text{NH}_2\text{OH})_2 \cdot \text{H}_2\text{SO}_4$. Granulated cadmium acts in a similar manner producing small quantities of hydroxylamine from nitric acid in the presence of sulphuric or hydrochloric acid. V. H. Veley, and H. E. Armstrong believe that nitrous acid is a primary product of the nitric acid whatever be the nature of the reducing agent—hydrogen or metal, or arsenious oxide—and that nitrous acid is invariably formed when any metal is dissolved in nitric acid. E. Divers, on the contrary, regards nitrous acid as a secondary product of the reaction:

When zinc acts upon nitric acid, neither nitrate nor nitrite or nitrous acid is the primary product, but rather nitrate and hydroxylamine, or ammonia, or nitrous oxide, or nitrogen, or, rather, all these together, but independently and each associated only with the nitrate. If zinc is left in nitric acid, there is undoubtedly a production of nitrite or nitrous acid, which may at last be considerable, but only as a secondary product. Zinc acts freely upon its own nitrate in aq. soln., the products being hydroxide and nitrite. Therefore, only in proportion as nitrate increases in quantity and, before all, nitric acid decreases in quantity, does nitrite or nitrous acid make its appearance.

Although ammonia is produced as a primary product of the reduction, E. Divers showed that it can also be formed as a secondary product as when in the absence of much free acid, hydroxylamine salts, or zinc nitrite, are reduced by zinc to ammonia; nitrous oxide is not only a primary product but it may also arise from the interaction of hydroxylamine with nitrous acid when one of these compounds is formed at a late stage in the reaction and finds the other present, although "they can hardly be supposed to be produced together only to become nitrous oxide and water." Similar remarks apply to nitrogen derived from the interaction of ammonia and nitrous acid. Nitrogen peroxide, and nitric oxide are also assumed to be secondary products derived from the decomposition of nitrous acid respectively by nitric acid and by water. A. von Bijler showed that when $\frac{1}{10}N$ -nitric acid acts on zinc at 25° , the ratio of ammonia to the dissolved zinc is as 1 : 35; while the equation: $4\text{Zn} + 10\text{HNO}_3 = 4\text{Zn}(\text{NO}_3)_2 + \text{NH}_4\text{NO}_3 + 3\text{H}_2\text{O}$, requires a ratio between 1 : 15 and 1 : 16; he attributes the difference to the formation of nitrous acid—no hydroxylamine was observed.

F. Novak found that zinc which has been annealed at 273° dissolves more rapidly in nitric acid than unannealed zinc rolled at 120° . Increasing the amount of lead in the zinc from 0.5 to 2.0 per cent. has very little effect on the speed of dissolution. The cadmium content of zinc conditions the speed of dissolution of the metal. W. W. J. Nicols, A. Krefling, A. Wagner, A. J. C. Snyders, and W. Smith found that soln. of **alkali nitrates** or **alkaline earth nitrates** attack zinc with the evolution of hydrogen. W. R. Hodgkinson and A. H. Coote found that the reaction with cadmium is faster than with zinc; and P. Forstner stated that the formation of alkali nitrite favours the dissolution of the metal. G. Arth found zinc dissolves in **Diver's liquid**, in a sealed tube, forming a crystalline mass. L. Loviton found zinc to be readily soluble in fused **ammonium nitrate** at 160° . W. R. Hodgkinson and A. H. Coote reported that cadmium reacts as fast with an aq. soln. of ammonium nitrate as with the molten salt; and in an ice-cold aq. soln., the metal dissolves without the evolution of any gas—the liquid has an alkaline reaction and gives off nitrogen at 100° . The soln. contains free ammonia and cadmium nitrite. The action of soln. of ammonium nitrate was also studied by A. Bringhenti.

B. Pelletier,¹⁰ and G. Landgrebe melted **phosphorus** with zinc and noticed the two elements combined; and several compounds have since been reported—*vide* phosphides. F. Stromeyer observed a similar behaviour with cadmium and phosphorus. E. Soubeiran,¹¹ and T. Bergman prepared compounds of zinc and **arsenic**. According to A. Vogel, when a mixture of the two elements is heated, combination sets

in before the mixture gets red hot, and the whole mass glows vividly with a dark red light, and some arsenic volatilizes. According to A. F. Gehlen, a mixture of arsenious oxide with twice its weight of zinc filings, reacts explosively when heated. K. Friedrich and A. Leroux studied a portion of the f.p. curve.

W. Heike obtained the f.p. curves shown in Fig. 17. There are two compounds, Zn_3As_2 , melting at 1015° ; and ZnAs_2 , melting at 771° . The former suffers a reversible transformation at 672° into a second modification. Otherwise the curves explain themselves. The alloys have a strong tendency to segregate. A. Descamps prepared some cadmium-arsenic alloys, and S. F. Schemtschuschny obtained the results shown in Fig. 18. The results, so far as they go, resemble

FIG. 17.—Freezing-point Curve of the Binary System: Zn—As.

FIG. 18.—Freezing-point Curve of the Binary System: Cd—As.

those with the zinc-arsenic alloys. There are two compounds, Cd_3As_2 , melting at 721° ; and CdAs_2 , melting at 621° . W. Spring found that a mixture of powdered arsenic and powdered zinc or cadmium forms an alloy when subjected to great press.

Alloys of antimony with zinc or cadmium are readily formed, and union occurs without the emission of light. The alloys are hard, and brittle, and have a steel-grey colour. The zinc-bismuth alloys were found by C. E. Gellert to have a smaller sp. gr. than the mean of the components. A. F. Gehlen, and A. Vogel also prepared alloys of zinc and antimony; and B. E. Curry, C. R. A. Wright, S. F. Schemtschuschny, H. Gautier and R. Gosselin, and K. Mönkemeyer studied the f.p. curves. The results are summarized in Fig. 19. There are two **zinc antimonides**, Zn_3Sb_2 and ZnSb . The curve shows one maximum, two eutectic points, and two m.p. of the pure metals. The evidence for the existence of the compound Zn_3Sb_2 is as follows. The curve exhibits a distinct maximum corresponding with 45 per cent. of zinc. At 561° , the temp. corresponding with this maximum, the solid which separates is uniform. The crystallization of the fused masses, containing 50 and 40 per cent. of zinc respectively, ends at 411° and 539° respectively. The presence of the compound Zn_3Sb_2 is also deduced from the structure of the alloys, containing from 40 to 50 per cent. of zinc. The evidence for the existence of the compound ZnSb is as follows. The curve exhibits a maximum, corresponding with 35 per cent. of zinc, whilst at 544° , the temp. corresponding with this maximum, the solid which separates is uniform. The crystallization of the fused masses containing 40 and 30 per cent. of zinc respectively ends at 539° and 507° respectively. The structure of the alloys is also evidence for the existence of this compound. J. P. Cooke and E. Elsässer, B. E. Curry, etc., studied the crystalline form of zinc-antimony alloys; J. P. Cooke and E. Maey, the sp. gr.; C. B. Thwing, the thermal expansion; A. Ledebur, the heat of fusion; J. C. Beattie, the behaviour in a

magnetic field; E. Becquerel, W. Rolmann, and A. Seebeck, the thermal e.m.f.; A. Matthiessen, and A. Heil, the electrical resistance; M. Herschkowitsch, and N. A. Puschin, the difference of potential against $N\text{-ZnSO}_4$; C. T. Heycock and F. H. Neville, the depression of the f.p.; and A. Stock and W. Doht, and E. Wiederhold, the action of acids. P. Giraud, A. Heil, G. A. le Roy, and K. Mönkemeyer studied the properties of alloys of zinc and antimony along with another element. Alloys of antimony and cadmium have been prepared by B. Wood, P. Christofle, C. R. A. Wright, etc. The f.p. curves have been studied by N. S. Kurnakoff and N. S. Konstantinoff, C. T. Heycock and F. H. Neville, and by W. Treitschke, and the results are summarized in Fig. 20. Two **cadmium antimonides**, Cd_3Sb_2 and

FIG. 19.—Freezing-point Curve of the Binary System: Sb—Zn.

FIG. 20.—Freezing-point Curve of the Binary System: Sb—Cd.

CdSb , appear in the diagram, the f.p. curve for cadmium and antimony takes a different form, according to the conditions of solidification, as, for instance, the nature of the substance covering the metals, the stirring of the mass, the presence of corresponding crystals, etc.; the two latter conditions being necessary for the formation of stable compounds at certain conc. The curve corresponds with four solid phases: (1) antimony, the eutectic point being at 445° and 58.4 per cent. Sb when crystals of the compound CdSb have been added previously, otherwise this part of the curve extends to 402° and composition 52.5 per cent. Sb. (2) The compound CdSb , which separates at 455° from liquid alloys when stirred and cooled quickly. If these alloys are allowed to cool slowly under a layer of carnallite, then the unstable compound Cd_3Sb_2 is formed. (3) The compound Cd_3Sb_2 , which commences to separate at 409° . (4) Free cadmium at the eutectic point 296° and 92.5 per cent. cadmium. The alloys containing 42 to 52.5 per cent. antimony, when already solidified, develop heat at 260° to 290° , the temp. rising suddenly by 20° to 30° ; this occurs most markedly for alloys containing 50 per cent. antimony, and also for those still richer in antimony if crystals are not added previously and the mass is not stirred while cooling, this sudden rise in temp. being due to the compound Cd_3Sb_2 passing into a more stable form, thus: $\text{Cd}_3\text{Sb}_2 + \text{Sb} = 3\text{CdSb}$. These views are fully confirmed by the microstructure of the various alloys, photographs of which were studied. At conc. 7.5–36 per cent. antimony, the compound Cd_3Sb_2 separates whatever the conditions. E. Maey studied the sp. gr. and the sp. vol. of cadmium-antimony alloys; J. C. Beattie, the behaviour in a magnetic field; C. B. Thwing, E. Becquerel, and A. Battelli, the thermal e.m.f.; W. Iskull, and N. S. Kurnakoff and N. S. Konstantinoff, the crystalline structure.

L. W. Cramer said that zinc does not alloy with **bismuth**. C. M. Marx reported that when equal parts of the two elements are melted together, two layers are

formed. J. Fournet said no chemical compound is formed. The alloys of zinc and bismuth have been studied by F. C. Calvert and R. Johnson, C. R. A. Wright and C. Thompson, etc. The f.p. curve of zinc and bismuth has been studied by C. T. Heycock and F. H. Neville, H. Gautier and R. Gosselin, B. E. Curry, W. Spring and L. Romanoff, and by P. T. Arnemann. The results are illustrated in Fig. 21. The alloy separates into two layers, a soln. of bismuth in zinc and of zinc in bismuth. The course of the two solubility curves is shown by the dotted curve in Fig. 21. It was studied by C. R. A. Wright, B. E. Curry, H. Gautier and R. Gosselin, F. Guthrie, and W. Spring and L. Romanoff. The latter found :

	266°	419°	475°	584°	650°	750°
Upper layer (Zn in Bi) .	—	97.0	95.0	90.0	85.0	73.0 per cent.
Lower layer (Bi in Zn) .	86.0	—	84.0	80.0	77.0	70.0 „

and the two elements are completely miscible at 850°. The sp. gr. and sp. vol. of zinc-bismuth alloys was studied by E. Maey, and H. Gautier; the heat of fusion by G. G. Person; the lowering of the f.p. by C. T. Heycock and F. H. Neville; the thermal e.m.f. by E. Becquerel, W. Rolmann, and A. Seebeck; the potential against $N\text{-ZnSO}_4$ soln. by M. Herschkowitsch, and A. Sucheni, and against a soln. of sodium chloride by A. P. Laurie and H. le Chatelier; and the action of nitric acid by C. Montemartini and E. Colonna. G. W. A. Kahlbaum and E. Sturm obtained an alloy by the compression of the mixed powders. The f.p. curve of the alloys of cadmium and bismuth has been studied by A. W. Kapp, and by A. Stoffel, with the results shown in Fig. 22. This is a typical V-eutectic curve. The alloys

FIG. 21.—Freezing-point Curve of the Binary System : Bi—Zn.

FIG. 22.—Freezing-point Curve of the Binary System : Bi—Cd.

have been studied by C. R. A. Wright, H. Behrens, and F. Guthrie. A. Matthiessen, G. Vicentini and D. Omodei, F. Rudberg, and E. Maey investigated the sp. gr. and sp. vol. of the cadmium-bismuth alloys; C. T. Heycock and F. H. Neville, and P. Siloff, the lowering of the f.p.; the thermal e.m.f. by C. C. Hutchins, A. Battelli, and D. Mazzotto; and M. Herschkowitsch, the difference of potential against $N\text{-CdSO}_4$ soln. E. Becquerel, and J. C. Beattie studied the ternary alloys Cd—Bi—Sb ; and C. R. A. Wright, and W. D. Bancroft, Cd—Bi—Zn .

B. Reinitzer and H. Goldschmidt¹² found that zinc reacts with **phosphoryl chloride** at ordinary temp. and more rapidly at 100°, forming zinc chloride, zinc metaphosphate, and a red substance—red phosphorus or phosphorus suboxide. Zinc reacts with **phosphoric acid**, forming the phosphate and phosphide. A. Brighenti, A. Krefting, and A. J. C. Snyders studied the action of soln. of the **alkali phosphates**. W. Smith found that with a boiling soln. of **ammonium phosphate**, zinc gives hydrogen and ammonia; and with a boiling soln. of **ammonium arsenate**, it gives hydrogen and arsine. A. Krefting studied the action of soln. of **sodium arsenate**, **sodium tungstate**, and **potassium antimonate**. W. Thomson found that the electrolytic reduction of soln. of **arsenites** or **arsenates** proceeds more rapidly with a zinc than with a lead cathode.

As previously indicated nearly all commercial zinc contains some **carbon**, which J. J. Berzelius,¹³ F. A. C. Gren, and R. Schindler assumed to be present as **zinc carbide**; the black powder which remains after the distillation of zinc cyanide, and which when ignited burns, forming zinc oxide, was also supposed by J. J. Berzelius to be zinc carbide. There is, however, no evidence of the formation of a carbide under these conditions. O. Ruff and B. Bergdahl found that cadmium and zinc dissolve only traces of carbon. M. Berthelot heated zinc with **carbon monoxide** in a sealed tube at 550° for many hours, and obtained a trace of carbon dioxide and carbon; **carbon dioxide** acts as an oxidizing agent on zinc vapour—*vide* the preparation of zinc. According to F. Wöhler, a soln. of **sodium carbonate** forms a soluble basic carbonate, NaO.Zn.NaCO_3 , and hydrogen is evolved. W. Smith found a boiling soln. of sodium carbonate was decomposed by zinc, forming hydrogen and zinc oxide; but, unlike F. Wöhler, he could find no zinc in the soln.; nor did H. W. F. Wackenroder find any attack on zinc oxide by a boiling soln. of sodium carbonate. A. Bringhenti studied the action of soln. of **ammonium carbonate**, and of **ammonium oxalate**. G. A. Goyder found that zinc dissolves in an aq. soln. of **potassium cyanide** with the evolution of a gas; the reaction has been studied by F. Kunschert, F. Spitzer, and H. A. White. A. Brochet and J. Petit found that under the influence of the alternating current, the attack by potassium cyanide results in the evolution of hydrogen, but it is arrested on account of the formation of a sparingly soluble complex salt $\text{ZnCy}_2 \cdot 2\text{KCy}$; with cadmium, the attack is continued by the aid of atm. oxygen and is concentrated on the portion of the strip near the surface of the liquid. A. Krefling studied the action of soln. of **potassium ferrocyanide**, and of **potassium ferricyanide**. Differences of electric potential of different parts of a piece of zinc or cadmium are shown by dipping the metal in an agar-gel containing potassium ferrocyanide and phenolphthalein. A. Bringhenti studied the action of soln. of **ammonium thiocyanate** and of **potassium thiocyanate**. According to G. Chesneau, dil. **acetic acid** attacks zinc more than does a *N*-soln. of **sodium acetate**. S. H. Mathews found that a soln. of **trichloroacetic acid** in nitrobenzene acts vigorously on zinc. Zinc is attacked by **carbon tetrachloride** in the presence of moisture, but **dichloroethylene**, **trichloroethylene**, and **perchloroethylene** are virtually inactive.¹⁴ N. N. Beketoff found **silicon tetrachloride** vapour is reduced to silicon and **boron trifluoride** is reduced to boron.

Zinc dissolves slowly in **alcohol**, and, according to T. Roman and G. Delluc,¹⁵ 0.006 grm. of zinc is dissolved per litre. M. Traube showed that absolute alcohol is not oxidized in air by zinc, but when diluted with water oxidation occurs, and this the more, the greater the proportion of water present. W. Ipatjeff, and H. Jahn have studied the action of zinc as a catalytic agent in the oxidation of alcohol to aldehyde, and the former found this metal is more active than copper, nickel, cobalt, iron, manganese, or chromium. Acetaldehyde is converted by zinc at an elevated temp. into carbon monoxide and methane. The effect of zinc on alcoholic liquids—wine, beer, and spirits—has been investigated by R. P. Duchemin, F. Malméjac, G. Heinzelmann, L. A. Levat, L. Nathan and A. Schmidt, and C. Sellenscheidt. The **fatty acids** were found by J. Pässler¹⁶ to attack zinc slowly. A. Mailhe studied the oxidation products. Z. Crommydis found that in the presence of zinc **oxalic acid** is reduced to glycollic acid. J. J. Redwood, and C. Engler and E. Kneis, found that zinc is not affected by **mineral lubricating oil**; the former also found that zinc is very little affected by **rape oil**, **olive oil**, or **tallow oil**; it is attacked most by **sperm oil**, less by **cotton-seed oil**, and less still by **lard oil**; but W. van Rijn found that zinc is attacked by olive oil and **castor oil**, and that **sesame oil** in a zinc vessel formed zinc palmitate, oleate, and stearate. A. Gawalowsky found zinc is but little attacked by rape oil. S. Fokin found zinc acts catalytically on the oxidation of **linseed oil**. D. Klein and A. Berg found a soln. of **sugar** at 115°–120° attacks zinc with the evolution of hydrogen, and the development of an acid; and F. Plzak and B. Husek found that the presence of zinc in palladium

makes the alloy retard the inversion of cane-sugar. Zinc was found by C. O. Weber to have very little action on sulphuretted caoutchouc.

A. Pospeloff¹⁷ found the vapour of zinc attacked the **platinum** electrodes in a discharge tube, but not **iron** or **aluminium** electrodes. In his study on **metallic precipitation**, N. W. Fischer noted that zinc or cadmium precipitates the metals from most of the ordinary salts of copper, silver, gold, cadmium (by zinc only), mercury, tin, lead, tellurium, bismuth, arsenic, antimony, iron, platinum, palladium, rhodium, iridium, and osmium, but not nickel—*vide* the individual metals, and the observations of J. A. Poumarède, L. de Boisbaudran, A. Destrem, and A. Villiers and F. Borg. In some cases, the metallic precipitation is utilized in quantitative analysis. E. Witting, J. B. van Mons, and J. B. Senderens found that zinc reduces lead from a soln. of lead acetate. T. E. Thorpe found that the reducing action of a definite amount of zinc on ferric salts increases with increased conc. and decreasing acidity of the soln. H. Munk found that zinc which has been in contact with a dil. soln. of alkali carbonate for a long time becomes more electronegative and precipitates copper from soln. less rapidly than ordinary zinc. Copper is precipitated from a soln. of copper oleate in cresol at 100°, and the addition of water favours the reaction; manganese, chromium, nickel, cobalt, iron, and cadmium were found by J. L. Sammis to be ineffective. For the action of soln. of **chromic acid** and **chromates** *vide* passive zinc. As W. R. Grove and others have shown, zinc may be regarded as an energetic **reducing agent**—particularly when in a powdered form—*e.g.* it reduces the chromates and permanganates; and with it C. Stahlschmidt reduced nitrates to nitrites; M. Delépine reduced tungstic oxide to tungsten; L. Troost reduced sodium zirconium chloride; and M. Dullo reduced sodium aluminium chloride. Powdered zinc has been much used as a reducing agent in organic chemistry. In the theory of the nascent state, the formation of hydrogen precedes the reduction, so that the reduction is due to a secondary reaction following the main reaction. J. Swinburne claimed that when zinc reacts with acid so as to reduce a ferric salt, it is better to say that when the metal dissolves it can either reduce a ferric salt or generate hydrogen. Of the two reactions, the reduction of the ferric salts consumes the less energy and so takes place. If no reducible salt be available, hydrogen gas is evolved, and much work is needed for its expansion, against atm. press., into the gaseous form.

If a piece of metallic zinc be immersed in a one per cent. soln. of copper sulphate, copper is precipitated on the zinc. When the zinc has been coated with a layer of copper, it can be removed from the soln., washed with water, and dried. The mixture of copper and zinc is called a **copper-zinc couple**.¹⁸ The couple can also be made by heating a mixture of nine parts of powdered zinc with one part of powdered copper in a flask until the zinc begins to flow. Let the mixture cool in a closed flask. The zinc is now much more active chemically, for, unlike metallic zinc alone, it can decompose water at ordinary temp. The zinc and copper act electrolytically. Metals which are chemically combined or alloyed together do not act in the same way. The two metals, one deposited upon the other, form a galvanic couple. The zinc-copper couple also reduces hydroxylamine hydrochloride to ammonium chloride, nitrates and nitrites to ammonia; chlorates to chlorides; arsenates to arsine, etc. The couple is also an important reducing agent in organic chemistry.

The metallic precipitation of zinc and cadmium.—S. Kern,¹⁹ and F. Faktor stated that metallic zinc is precipitated from soln. of its salts by *magnesium*, and with a conc. soln. of zinc chloride much hydrogen is evolved. With a hot or cold, conc. or dil. soln. of zinc sulphate, E. G. Bryant obtained about a 50 per cent. yield of metallic zinc. H. N. Warren made a *zinc-tree*, by wrapping a magnesium rod in asbestos paper, and immersing the roll in a soln. of zinc chloride. W. Eidmann found that the decomposition of zinc cyanide by magnesium is vigorous, and is accompanied by incandescence, forming magnesium nitride, zinc, and carbon. G. McP. Smith found a conc. soln. of zinc cyanide gives a precipitate of zinc when

treated with *copper*. According to K. Seubert and A. Schmidt, G. Post, and A. J. C. Snyders, when a neutral aq. soln. of zinc chloride is treated with *zinc* filings, zinc hydroxide and a basic chloride are formed; while an ammoniacal soln. gives a precipitate of zinc and zinc hydroxide, but about 20 per cent. of zinc remains in soln.; the precipitation is also incomplete with hydrochloric acid soln. M. Centnerszwer and J. Drukker measured the rate of precipitation of copper from soln. of cupric sulphate by zinc. They found evidence of a period of induction, and that if C denotes the conc. of the copper in soln., and C' , the conc. of the copper at the surface of the metal, while x denotes the amount of copper precipitated by a zinc plate of surface S , then $dx/dt = kS(C - C')$. If the reaction at the surface of the zinc is instantaneous, $C' = 0$. If C_0 denotes the initial conc. of the soln., and v its vol., $x = (C_0 - C)v$, and $dx/dt = -v dC/dt$. Hence, $-vdC/dt = kSC$, or $k = 2.303v(\log C_0 - \log C)/St$. J. L. Davis also studied the precipitation of metals by zinc.

F. Faktor²⁰ found that cadmium hydroxide is precipitated when a soln. of a cadmium salt is treated with *magnesium*—hydrogen is at the same time evolved. C. Formenti and M. G. Levi found that *aluminium* energetically reduces an aq. soln. or a molten cadmium salt; C. Goldschmidt found that cadmium is quantitatively precipitated by boiling in a vessel of aluminium an aq. soln. of a cadmium salt, mixed with a little cobalt or chromium nitrate. G. McP. Smith observed that *copper* precipitates cadmium from a conc. aq. soln. of cadmium sulphate in potassium cyanide. P. N. Raikow and O. G. Georgiew found that powdered *iron* forms a ferrous salt when treated with a neutral soln. of cadmium nitrate, sulphate, chloride, bromide, or iodide, but not the chlorate. J. L. Sammis found that *lead* is covered with a black film when boiled for 2 hrs. with a soln. of cadmium oleate in toluene, while magnesium, aluminium, antimony, bismuth, zinc, cadmium, tin, iron, nickel, cobalt, copper, or silver does not act in this way.

The electrodeposition of zinc and cadmium.—The electrodeposition of zinc from *neutral solutions* has been investigated by A. Minet,²¹ C. J. Zimmermann, F. F. Exner, etc.; of cadmium from neutral soln. by A. Hollard,²² H. Senn, E. F. Smith, A. Classen, A. Fischer, etc.; of zinc from *acid solutions* by T. S. Price,²³ W. D. Bancroft, S. Cowper-Coles, etc.; of cadmium from acid soln. by C. Luckow,²⁴ A. Classen, S. Avery and B. Dales, M. Heidenreich, E. F. Smith, etc.; of zinc from *cyanide solutions* by C. Luckow,²⁵ F. Beilstein and L. Jawein, M. le Blanc and K. Schick, etc. C. J. Werlund recommended the following cyanide bath for zinc plating, the values being oz. per gallon: $Zn(CN)_2$, 8; NaCN, 7; NaOH, 1 or 2; Na_2CO_3 , 4; NaF, 1; corn syrup, 1; gum arabic, $\frac{1}{4}$; temp. of bath, 40°–50°; voltage, 3–5. Very smooth, greyish-white deposits were obtained. The electrolyte does not deteriorate on standing, and can be used with a high current density even in mechanical plating units where the cleaning is poor. The electrodeposition of cadmium from cyanide soln. has been investigated by A. Brunner,²⁶ A. Fischer, W. Stortenbecker, etc.; of zinc from *solutions of alkali zincates* by F. Weil,²⁷ C. Beslay, W. D. Bancroft, F. Förster and O. Günther, etc.; of cadmium from alkali soln. by W. S. Lorimer and E. F. Smith,²⁸ E. F. Smith and F. Muhr, T. Moore, etc.; and of zinc from *ammoniacal solutions* by F. Förster and co-workers,²⁹ T. S. Price, L. H. Ingham, etc. The effect of various additions to the electrolyte have been tried; for instance, F. Förster and O. Günther³⁰ tried a soln. of zinc chloride sat. with zinc oxychloride; J. Rontschewsky, chloric acid; H. Paweck, boric acid or borates, C. F. Burgess, C. C. Person, L. Potthoff, A. van Winkle, E. Kaselowsky, and G. Langbein, aluminium salts; A. Schaag and co-workers, J. Szirmay and L. von Kollerich, and R. de Montgelas, magnesium salts; C. F. Burgess, A. Schaag and R. Falk, G. Langbein, O. Gabran, and O. Lehmann, tin salts; H. Leitner, manganese salts; S. Cowper-Coles, iron salts; and J. Burrow, A. Schaag and R. Falk, mercuric salts. W. D. Bancroft found the presence of cadmium, iron, lead, and copper produces bad results because these metals may be deposited before the zinc. The addition of several organic

compounds or salts of organic acids has been tried: A. van Winkle, gelatine; J. Szirmay and L. von Kollerich, dextrose; W. D. Bancroft, glue; J. Meurant, gum; A. Classen, and S. A. Tucker and E. G. Thomssen, glucosides; G. Langbein, dextrose; A. Brester, L. Trunkhain, sugar (maltose and dextrose) and yeast; L. Potthoff, A. Schaag and co-workers, acetic, citric, or tartaric acid; E. C. Broadwell, phenol, aldehyde, carboxylic acids; E. D. Kendall, glycerol; W. D. Bancroft, formaldehyde; G. Langbein, urea; and E. Goldberg, amines, amides, cyanides, nitriles, and pyridine and quinoline bases. A. Mazzucchelli found, with a low current density, small additions of salts of quinine, cinchonine, quinoline, dimethylaniline, α -naphthylamine, lutidine, aniline, pyridine, and gelatin, using a zinc anode, and a brass cathode, homogeneous, uniform, and fine-grained deposits of zinc can be obtained. Q. Marino electrolyzed soln. of zinc salts in glycerol; and H. E. Patten, soln. of zinc salts in acetone. G. Carrara electrolyzed methyl alcohol soln. of cadmium salts.

The electrolysis of molten zinc chloride and iodide was studied by M. Faraday in 1833; and the work has been extended by R. Lorenz³¹—with and without additions of ammonium, potassium, sodium, or magnesium chloride. The effect of other chlorides—lead, iron, copper, and silver—has been tried. J. Swinburne,³² R. Lorenz and co-workers, O. H. Weber, A. Helfinstein, H. Frei, etc., electrolyzed fused cadmium chloride. V. Czepinsky has studied the electrolysis of zinc bromide; and O. H. Weber, of cadmium bromide. The *alternating current electrolysis* of zinc salts has been investigated by B. Rösing,³³ M. le Blanc and K. Schick, A. Löb, etc.; and of cadmium salts by J. W. Richards,³⁴ M. le Blanc and K. Schick, A. Löb, A. Brochet and J. Petit, H. Danneel, etc. The choice of *anodes* has been studied by J. W. Langley,³⁵ G. Langbein, A. G. Betts, etc., and the choice of *cathodes* by A. Gockel,³⁶ H. Nissenson, H. Paweck, etc.

Reactions of zinc and cadmium of analytical interest.—Neither zinc nor cadmium salts give a precipitate with hydrochloric acid, and zinc does not give a precipitate with **hydrogen sulphide** in acid soln., although cadmium salts give a yellow precipitate of cadmium sulphide, which, unlike the yellow precipitate of arsenic sulphide, is insoluble in alkali sulphides, soluble in a large excess of hydrochloric acid, in warm dil. nitric acid, or boiling dil. of sulphuric acid (1:5). According to F. Jackson,³⁷ one part of cadmium in 16,000 parts of soln. can be detected by hydrogen sulphide. A neutral soln. of a zinc salt precipitates zinc sulphide incompletely when treated with hydrogen sulphide, $\text{ZnCl}_2 + \text{H}_2\text{S} \rightleftharpoons 2\text{HCl} + \text{ZnS}$; the precipitate is soluble in mineral acids, so that the reaction is reversible. Zinc sulphide is insoluble in acetic acid, so that if the soln. of zinc salt contains sodium acetate, the zinc may be quantitatively precipitated by hydrogen sulphide: $\text{ZnCl}_2 + 2\text{NaC}_2\text{H}_3\text{O}_2 + \text{H}_2\text{S} = 2\text{NaCl} + 2\text{HC}_2\text{H}_3\text{O}_2 + \text{ZnS}$. Similar remarks apply to weaker acids other than acetic.

Neutral or alkaline soln. of zinc salts give a colloidal precipitate of zinc sulphide when treated with **ammonium sulphide**: $\text{ZnCl}_2 + (\text{NH}_4)_2\text{S} = \text{ZnS} + 2\text{NH}_4\text{Cl}$. The precipitate is more granular and more easily filtered and washed if it be obtained with boiling soln. in the presence of a considerable proportion of ammonium salts, so that hydrogen sulphide or an alkali sulphide gives a precipitate in an ammoniacal soln. of a zinc salt. According to J. L. Lassaigne, one part of zinc sulphate in 10,000 parts of water gives flakes of the sulphide with potassium sulphide, and with 20,000 parts of water, a faint opalescence. F. Jackson said that one part of zinc in 8000 parts of soln. can be detected by means of ammonium sulphide. According to B. Neumann, and E. Mylius, the ferrocyanide reaction for zinc is more sensitive than that with ammonium hydroxide, carbonate, or hydrosulphide, especially working with hot soln. and avoiding an excess of the precipitant. E. Jordis gave the sensitiveness as 1 in 3,000,000. Cadmium salts under similar conditions give a yellow colloidal cadmium sulphide which is coagulated if it be formed in a conc. salt soln. When zinc salts are treated with **alkali** a white gelatinous hydroxide is precipitated which is soluble in excess, forming a soln. of alkali zincate, say, $\text{Zn}(\text{OK})_2$; when a dil. aq.

soln. of the alkali zincate is boiled, hydrolysis occurs, and zinc hydroxide is precipitated. The corresponding hydroxide precipitated from cadmium salts by alkali hydroxides, is not soluble in an excess, and when gently ignited, furnishes a brown-coloured oxide. F. Jackson found that one part of zinc or cadmium in 4000 parts of soln. can be detected by sodium hydroxide. Aq. **ammonia** precipitates white zinc hydroxide from neutral soln. The precipitate is soluble in ammonium salts because of the formation of a soluble complex salt; zinc hydroxide is also soluble in an excess of ammonia because of the formation of a soluble complex salt, $[\text{Zn}(\text{NH}_3)_6](\text{OH})_2$; and in the presence of ammonium salts, say, ammonium chloride, the soluble complex $[\text{Zn}(\text{NH}_3)_6]\text{Cl}_2$ is formed. Similar results are obtained with nickel, manganese, magnesium, or iron salts. Ammonia also precipitates white cadmium hydroxide which, unlike lead hydroxide, is soluble in an excess owing to the formation of a soluble complex hexammino-salt as in the case of zinc. When the soln. of the complex is diluted and boiled, cadmium hydroxide is re-precipitated. According to F. Jackson, soln. containing one part of zinc in 8000 and one part of cadmium in 4000, give precipitates with aq. ammonia; T. G. Wormley said one part of zinc in 12,500 can be detected by aq. ammonia.

A white basic carbonate, like the corresponding magnesium compound, is precipitated on adding an **alkali carbonate** to a soln. of a zinc or cadmium salt. The precipitate is not soluble in excess. According to J. L. Lassaigne, a soln. of one part of zinc sulphate in 10,000 parts of water gives flakes of the precipitate with sodium or potassium carbonate, but with 20,000 parts of water the precipitate appears only after some time. T. G. Wormley detected one part of zinc in 12,500 parts of soln. by means of sodium carbonate, and F. Jackson one part of zinc in 8000 parts of soln., and one part of cadmium in 4000 parts of soln. A soln. of **ammonium carbonate** behaves in a similar manner; except that the precipitate with the zinc salt is soluble in excess, but insoluble with the cadmium salt, the precipitation does not occur in the presence of ammonium chloride. According to J. N. von Fuchs, zinc salts are not precipitated by calcium carbonate, but, according to H. Demarçay, although zinc salts give no precipitate with **barium carbonate**, if the mixture is boiled, all the zinc is precipitated as basic carbonate. Similar remarks apply to the carbonates of strontium, calcium, and magnesium. Zinc sulphate of course decomposes barium carbonate. Cadmium salts are not changed.

When a soln. of a zinc salt is treated with **potassium cyanide**, a white precipitate of zinc cyanide is formed: $\text{ZnCl}_2 + 2\text{KCy} = 2\text{KCl} + \text{ZnCy}_2$, which is soluble in excess owing to the formation of a soluble complex, K_2ZnCy_4 . This complex is decomposed by acids: $\text{K}_2\text{ZnCy}_4 + 2\text{HCl} = 2\text{KCl} + 2\text{HCy} + \text{ZnCy}_2$; and by alkali sulphides: $\text{K}_2\text{ZnCy}_4 + (\text{NH}_4)_2\text{S} = 2\text{KCy} + 2\text{NH}_4\text{Cy} + \text{ZnS}$. Cadmium salts also give white cadmium cyanide under similar conditions, and this too is soluble in excess owing to the formation of a soluble complex, K_2CdCy_4 . Alkali hydroxides and carbonates do not give a precipitate with a soln. of potassium cadmium cyanide, but hydrogen sulphide precipitates yellow cadmium sulphide. F. Jackson detected one part of cadmium in 1000 parts of soln. by means of potassium cyanide. When zinc salt soln. are treated with **potassium ferrocyanide**, they furnish a white precipitate of zinc ferrocyanide, Zn_2FeCy_6 , which is changed by an excess of the potassium salt into insoluble potassium zinc ferrocyanide, $\text{Zn}_3\text{K}_2(\text{FeCy}_6)_2$. According to J. L. Lassaigne, one part of zinc sulphate in 10,000 parts of water gives a slight turbidity with potassium ferrocyanide; with 20,000 parts of water a very slight turbidity; and with 80,000 parts of water, the turbidity does not appear until after 5 to 10 mins. When **potassium ferricyanide** is added to a soln. of a zinc salt, a brownish-yellow precipitate of zinc ferricyanide is formed which is soluble in ammonia and in moderately conc. hydrochloric acid. No precipitate is formed when a soln. of a cadmium salt is treated with **potassium thiocyanate** alone or after the addition of sulphurous acid. **Ammonium thioacetate** gives no precipitate with zinc salts in acid soln., but zinc sulphide is precipitated from ammoniacal soln. When zinc salts are treated with **sodium phosphate** they furnish a gelatinous precipitate

of normal zinc phosphate: $4\text{Na}_2\text{HPO}_4 + 3\text{ZnCl}_2 = 2\text{NaH}_2\text{PO}_4 + \text{Zn}_3(\text{PO}_4)_2 + 6\text{NaCl}$; the precipitate soon becomes crystalline and then filters readily; it is soluble in ammonia and in acids. Cold soln. of cadmium salts gives no precipitate with **potassium chromate**, but a boiling soln. gives a precipitate of yellow basic chromate, $\text{Cd}_2(\text{OH})_2\text{CrO}_4$. F. Jackson said that one part of cadmium in 1000 parts of soln. can be detected by the precipitate produced with potassium dichromate. Cadmium salts give no precipitate with chromic acid. Cadmium and zinc salt soln. give no precipitate with **sodium thiosulphate**, or with **sodium sulphite**. S. R. Benedict obtained a white precipitate when **potassium periodate** is added to a soln. of a zinc salt. The presence of ammonia hinders the precipitation. A 17 per cent. soln. of **potassium perchlorate** was found by R. Salvadori to give a white crystalline precipitate with ammoniacal soln. of cadmium salts. A. del Campo Cerdan reported that when an alcoholic or ethereal soln. of **resorcin** is added to ammoniacal soln. of resorcin a blue coloration is produced. The reaction is characteristic if salts of cadmium, copper, cobalt, nickel, or manganese be absent. A soln. of **potassium oxalate** produces a white crystalline precipitate with a soln. of a zinc salt; the resulting zinc oxalate forms a soluble double salt with an excess of the precipitant; and the double salt is decomposed by acetic acid reprecipitating zinc oxalate. Alkali sulphates, acetates, formates, and succinates do not give precipitates with zinc salts, but a mixed precipitate is formed if some chromium salt is present as well.

The uses of zinc and cadmium.—Galvanizing is perhaps the most important use to which metallic zinc is put. In 1837, H. W. Cranfurd³⁸ coated well-cleaned surfaces of iron by simple immersion in a bath of molten zinc. The operation is called **galvanizing**, and the coated metal **galvanized iron**. Previously, iron was coated by galvanic agency, hence the name. Although the galvanic process was practically ousted by H. W. Cranfurd's process, the electrolytic process is a serious competitor, even though the surface is dull and dead and not so bright as in the hot immersion process. The advantages of the galvanic process turn on (i) greater economy in the use of the metal; (ii) better control of the thickness of the coating; and (iii) its use for special articles of steel, etc., whose temper would be injured by immersion in a bath of molten zinc.

In **dry galvanizing**, or **sheradizing**, the cleaned articles of iron or steel are heated in metal boxes or drums alone with zinc dust at a temp. between 260° and 425° . The zinc is partially volatilized, and the vapour condenses on the surface of the metal to be plated.³⁹ The sheradized surface is light grey and matt, but it can be polished to rival nickel plate. The process was devised by S. Cowper-Coles about 1902; it is adapted for coating articles with a pattern or design on the surface which would be filled up or obliterated by ordinary hot galvanizing. Metals, etc., can also be coated with a protective or ornamental film of some other metal by **spraying**. In Scoop's process⁴⁰ the spray is driven at a high velocity against the body to be coated.

Spelter is used for making ornamental slush or hollow castings where the metal is poured from the mould as soon as the surface has solidified. Rolled zinc plates are used for domestic articles; as an anti-corrosive agent in steam boilers where the zinc plates bolted to the boiler are attacked first and renewed as required. Cast zinc rods are used for batteries; seamless zinc pipes for cold-water supplies may be tin-lined. Zinc is cheaper than lead for this purpose, but the expansion is too great if hot water is to be transported. Zinc is used in the manufacture of a large number of alloys—*vide* brass. The addition of zinc to certain alloys gives them increased wearing powers, and it is therefore added to bearing metals, bronze coinage, etc.; and as a precipitant for gold in the cyanide process; it is also used in Parkes' process for desilvering lead; and in zincography. Zinc dust is employed as a reducing agent in the dyeing industry. Many of the compounds of zinc, such as the oxide, chloride, sulphate, and carbonate, are employed for a great variety of medicinal and industrial purposes. P. Drinker has reviewed the bibliography on the **toxicity of zinc**—*vide* zinc oxide. C. O. Johns and co-workers, and E. W. Schwartze and

C. L. Alsberg have also studied the physiological action of zinc and cadmium salts. J. Czochralsky and E. Lohrke have discussed the *zinc pyrophoric alloys*.

Cadmium is used in making low temp. melting alloys—tips of automatic sprinklers, safety plugs for boilers, electric fuses, stereotype plates, and solders. Cadmium is stated by C. E. Siebenthal and A. Stoll⁴¹ to be a better rust preventer than nickel, so that it has a greater tendency than nickel to tarnish. When alloyed with a little silver, it is used for plating the bright parts of bicycles, etc. An alloy of cadmium with 7.5 per cent. of silver withstands the influence of the atm. better than silver with an eq. amount of copper. A fraction of one per cent. of cadmium is used as a deoxidizer in making bronze telegraph and telephone wires and cables in France and Italy. It is also used as a deoxidizer in making nickel alloys. A cadmium band on the hard-jacketed cartridge ball of small arms ammunition, is said to take the rifling with little wear on the barrel, and thus prolongs the life of the gun. Cadmium amalgam was formerly used by dentists for stopping teeth. Cadmium sulphide is used for making yellow pigments, although it is too costly for general consumption.

§ 7. The Atomic and Molecular Weights of Zinc and Cadmium

J. J. Berzelius estimated that the at. wt. of zinc is about four times the hydrogen eq., 33, and zinc oxide, now symbolized ZnO, was symbolized ZnO₂. A number approximating to 65.4 for the at. wt. of zinc is in agreement with Dulong and Petit's sp. ht. rule; with Mitscherlich's isomorphic rule; with the periodic rule; and with the vap. density of the volatile compounds of zinc—e.g. according to V. and C. Meyer,¹ the vap. density of zinc chloride is of the order 131.2 to 133.5, which is in agreement with the at. wt. 65.4 as the smallest value for the at. wt. of zinc. A similar conclusion follows from the vap. density of zinc ethyl, and other volatile zinc compounds; and from the determinations of the mol. wt. of zinc salts in soln. Similar remarks apply also to cadmium for the different properties of this element,

and the vap. density of cadmium iodide, measured by A. Scott, corresponds approximately with the at. wt. 112.

According to O. Meyer and co-workers, the **vapour density** of zinc is between 2.36 and 2.41, when the calculated value for a monatomic mol. is 2.25; H. Biltz obtained 2.64 between 1732° and 1748°. H. von Wartenburg also measured the vap. density in argon between 1200° and 2070°, and obtained a mean value corresponding with a mol. wt. of 70.4. The monatomic nature of the zinc molecule is confirmed by A. F. Krafft and P. Lehmann's determination of the b.p. of zinc in vacuo in the cathode rays. J. Traube also inferred that molten zinc has monatomic mols. in proximity to the b.p. This is also confirmed by W. Vaubel, and G. G. Longinescu. P. Walden also came to the same conclusion from his work on the surface tension. From the f.p. of soln. of zinc in mercury G. Tammann assumed that the zinc in soln. has monatomic mols. G. Meyer, and G. McP. Smith came to a similar conclusion. C. T. Heycock and F. H. Neville also measured the depression of the f.p. of zinc in molten cadmium, lead, or bismuth. According to W. Broniewsky, at the lower temp. the zinc mol. probably becomes more complex because, like iron, cobalt, and nickel, its dilation and electrical resistance change up to a definite critical temp. at which the mols. become monatomic—similar discontinuities are obtained with the thermal e.m.f. and the sp. ht. P. Walden obtained 1.5 for the association factor; J. Traube, 1.0; W. Vaubel, 4.4; and G. G. Longinescu, 5.0.

H. St. C. Deville and L. Troost² found the vap. density of cadmium to be 3.94; H. Biltz, 4.34 to 4.38; the calculated value for a monatomic vapour is 3.87. G. Meyer, and H. Biltz and V. Meyer also obtained results in agreement with this assumption. A. F. Krafft and P. Lehmann assumed that the cadmium mol. is monatomic, from observations on the b.p. of the metal in vacuo when exposed to cathode rays. G. Meyer calculated the mol. wt. of cadmium from the difference in potential of two amalgams of different conc. in a soln. of potassium iodide, but F. Haber showed that it is not possible to distinguish by electrometry the difference in effects produced from monatomic mols. and the formation of complexes. W. Ramsay and G. McP. Smith obtained results in agreement with the assumption that the metal forms monatomic mols. when dissolved in mercury. G. Tammann drew a similar conclusion from the f.p. of soln. in mercury, and C. T. Heycock and F. H. Neville from soln. in bismuth or tin. From observations on the surface tension of fused cadmium, P. Walden concluded that the mols. of fused cadmium are probably monatomic. W. Broniewsky concluded that the cadmium mol. shows no association at -183°. P. Walden and J. Traube obtained 1.0 for the association factor; G. G. Longinescu, 3.0; and H. Siedentopf, 1.7.

J. L. Gay Lussac³ made the first determination of the at. wt. of zinc by oxidizing the metal in nitric acid and measuring the evolved hydrogen, but J. J. Berzelius, in 1811, dissolved zinc in nitric acid, evaporated the soln. to dryness, and calcined the residue. The results correspond with the at. wt. 64.51.

V. A. Jacquelin, in 1842, determined the ratio Zn:ZnO by converting the metal into nitrate, and igniting the nitrate for the oxide as done by J. J. Berzelius; he calculated from the Zn:ZnO, 66.23. A. Erdmann employed a similar process, and obtained 65.05; H. N. Morse and W. M. Burton likewise obtained 65.46; and H. N. Morse and H. B. Arbuckle, correcting the results for the occluded gases in the oxide, obtained 65.46. H. Baubigny converted the anhydrous sulphate into oxide by calcination, and calculated 65.4 from the ratio $\text{ZnSO}_4:\text{ZnO}$. P. A. Favre dissolved a known weight of zinc in dil. sulphuric acid and burnt the resulting hydrogen to water. He calculated the at. wt. 65.99 from the ratios $\text{Zn}:\text{H}_2:\text{H}_2\text{O}$. Like J. L. Gay Lussac, J. D. van der Plaats measured the vol. of the hydrogen evolved by treating a known weight of the metal with acid, and calculated the at. wt. 65.48 from the ratio $\text{Zn}:\text{H}_2$; H. C. Reynolds and W. Ramsay employed a similar method and obtained 65.78. J. W. Mallet likewise obtained 65.53. P. A. Favre ignited zinc oxalate, and weighed the resulting carbon dioxide; he calculated the at. wt. 66.02 from the ratio $\text{ZnC}_2\text{O}_4:\text{CO}_2$. J. C. G. de Marignac analyzed potassium

zinc chloride, K_2ZnCl_4 , and obtained 65.29 and 65.33 for the at. wt. of zinc. J. H. Gladstone and W. Hibbert determined the amounts of copper and silver precipitated from soln. of the respective salts by a given amount of zinc, and from the ratio $Zn : 2Ag$, obtained 65.44; and from the ratio $Zn : Cu$, 65.65. L. Meaglia likewise precipitated silver and gold from soln. of their salts, and obtained respectively 65.485 and 65.436. T. W. Richards and E. F. Rogers obtained respectively 65.402 and 65.43 from the ratio $ZnBr_2 : 2Ag$; and 65.406 and 65.43 from the ratio $ZnBr_2 : 2AgBr$. G. P. Baxter and M. R. Grose from the electrolysis of a soln. of zinc bromide with a mercury cathode obtained from the ratio $Zn : Br_2$, 65.388; and likewise from the ratio $Zn : Cl_2$, G. P. Baxter and J. H. Hodges obtained 65.38. A. L. Bernoulli calculated 65.569 for the at. wt. of zinc from thermodynamical data; and W. M. Watts 64.78 from the period of vibration of the spectral rays. B. Brauner calculated 65.40 as the best representative value for the at. wt. of zinc; F. W. Clarke computed 65.4182 with the probable error ± 0.00048 ; and the International Table of at. wt. for 1920 gives 65.37 for the at. wt. of zinc. The **atomic number** is 30.

F. Stromeyer⁴ determined the at. wt. of cadmium in 1818 by converting the metal into oxide by calcination, and calculated 111.49 from the ratio $Cd : CdO$. H. N. Morse and H. C. Jones, in 1892, converted a known weight of the metal into nitrate, and calcined the product for cadmium oxide. They calculated the at. wt. 112.06 from the ratio $Cd : CdO$; J. E. Bucher obtained at. wt. 112.08 and 111.87 when the nitrate was calcined respectively in porcelain and platinum dishes; H. N. Morse and H. B. Arbuckle obtained 112.38. K. von Hauer converted the anhydrous sulphate into sulphide by heating it in a stream of hydrogen sulphide, and from the ratio $CdSO_4 : CdS$ calculated 111.94 for the at. wt. of cadmium; E. A. Partridge likewise obtained 111.76 by converting the sulphate into sulphide, and 111.64 by converting the oxalate into sulphide, $CdC_2O_4 : CdS$. J. E. Bucher also obtained 112.11 from the ratio $CdC_2O_4 : CdS$. W. Blum converted the oxide into sulphide and calculated 112.69 from the ratio $CdO : CdS$. J. B. A. Dumas by titrating a soln. of a known weight of chloride with standard silver nitrate, obtained 112.31 from the ratio $CdCl_2 : 2Ag$; W. L. Hardin evaluated the ratio $CdBr_2 : 2Ag$ by electrolysis and computed 111.98; A. K. Huntington also computed 112.23 from the ratio $CdBr_2 : 2AgBr$, and 112.24 from the ratio $CdBr_2 : 2Ag$. J. E. Bucher computed 112.38 from the ratio $CdCl_2 : 2AgCl$, and 112.39 from the ratio $CdBr_2 : 2AgBr$. G. P. Baxter and M. A. Hines analyzed the chloride gravimetrically, and from the ratio $CdCl_2 : 2AgCl$ calculated 112.424; from the ratio $CdCl_2 : 2Ag$ obtained volumetrically, 112.409; G. P. Baxter, M. A. Hines, and H. L. Frevert likewise calculated 112.413 from the ratio $CdBr_2 : 2AgBr$, and 112.421 from the ratio $CdBr_2 : 2Ag$. E. A. Partridge obtained 111.80 from the ratio $CdC_2O_4 : CdO$; H. N. Morse and H. C. Jones, 112.02; and J. E. Bucher, 111.88. W. S. Lorimer and E. F. Smith calculated the at. wt. 112.06 from the ratio $CdO : Cd$ obtained by the electrolysis of a soln. of a known weight of the oxide in one of potassium cyanide. W. L. Hardin likewise calculated 112.06 from the ratio $CdCl_2 : Cd$ obtained by the electrolysis of a soln. of the chloride; G. P. Baxter and M. L. Hartmann, from the ratio $Cd : Cl_2$ obtained 112.405; G. P. Baxter, M. R. Grose, and M. L. Hartmann, from $Cd : Br_2$ obtained 112.407; and G. P. Baxter and C. H. Wilson, from the ratio $Cd : SO_4$ obtained 112.409. J. E. Bucher converted cadmium into sulphate, and calculated 112.36 from the ratio $Cd : CdSO_4$. L. Meaglia precipitated gold from a soln. of sodium chloraurate, and silver from a soln. of silver sulphate by means of cadmium, and from the two ratios calculated respectively 112.50 and 112.39. B. Brauner calculated 112.3 for the best representative value of the at. wt. of cadmium; F. W. Clarke, 112.402 ± 0.0008 ; while the International Table for 1922 gives 112.40. The **atomic number** is 48. A. J. Dempster found that zinc consists of four **isotopes** of respective atomic weights—64, 66, 68, and 70. The relative intensities in the same order are 6 : 7 : 10 : 1. From these atomic weights of the isotopes and the proportions in which they occur in ordinary zinc, the atomic weight of the latter is calculated to be 65.5. F. W. Aston's experiment with cadmium

vapour was not successful, and the isotopes were not identified. A. C. Egerton obtained a partial separation of zinc by fractional distillation since the ratios of the sp. grs. of the two fractions to that of the original metal were respectively 0.99971:1 and 1.00026:1.

§ 8. The Preparation of Zinc and Cadmium Oxides and Suboxides

When zinc is exposed to air at ordinary temp., it is soon covered with a thin grey film which protects the metal from further oxidation; molten zinc also rapidly oxidizes to a grey powder which soon forms the white oxide. J. J. Berzelius¹

assumed that the grey powder is **zinc suboxide**, while H. Davy said: "The grey powder formed upon the surface of melted zinc, I am inclined to consider as a mixture of the white oxide with small particles of unburnt zinc." J. L. Proust, and A. Vogel also regarded it as a mixture of metal and oxide. R. C. Schüpphaus obtained a permanent canary-yellow powder by heating zinc oxide with carbon under press. The analysis showed that more zinc was present than corresponds to the normal oxide. It was also obtained by heating zinc oxide in vacuo, or in an atm. of purified nitrogen; or by heating a mixture of zinc oxide and zinc under press. This product was thought to contain a suboxide, but is more probably a soln. of finely divided zinc in the oxide. L. Meyer and F. Binnecker assumed that an unstable zinc suboxide is formed as an intermediate compound when zinc sulphate acts as a stimulant in the oxidation of sulphur dioxide; they applied a similar argument to **cadmium suboxide**.

R. F. Marchand² obtained a green powder by heating cadmium oxalate to the m.p. of lead. Mercury extracts no metal from the product, and when heated in air, it vigorously oxidizes, forming a mixture of the brown oxide and the metal. R. F. Marchand's analysis corresponded with **cadmium hemioxide**, Cd_2O . A. Vogel, however, regarded the product as a mixture of the metal and of the oxide, which contains a larger proportion of metal, the higher the temp. of decomposition. A. Souchay and E. Lenssen also support this view. F. Glaser found that acetic acid dissolves the oxide and leaves microscopic spherules of the metal; nor could he obtain any signs of the suboxide by reducing the oxide in a stream of hydrogen. M. S. Tanatar and M. Levin described a hemioxide, Cd_2O , or maybe Cd_3O_2 , as a green powder which is produced by heating the basic oxalate, $\text{CdC}_2\text{O}_4 \cdot \text{Cd}(\text{OH})_2$. It is said to be decomposed by water, and it apparently resembles the product obtained by R. F. Marchand. H. N. Morse and H. C. Jones prepared what they regarded as **cadmium subhydroxide**, or **cadmium monohydroxide**, CdOH , by washing one of the so-called subhalides with warm water at a temp. not exceeding 50° . The amorphous grey mass gives off hydrogen when treated with hydrochloric and sulphuric acids, but with nitric acid, nitric oxide is formed. When the dried product is heated to about 300° in a stream of nitrogen, a heavy yellow powder of cadmium hemioxide is formed in microscopic crystals. If the temp. exceeds 300° , it is said that the hemioxide decomposes into cadmium oxide and the metal. F. J. Brislee argued that cadmium hemioxide is the first product of the reduction of cadmium oxide. If the reaction $\text{CdO} \rightarrow \text{Cd}_2\text{O}$ is faster than the reaction $\text{Cd}_2\text{O} \rightarrow \text{Cd}$, there must be a break in the time-reduction curve corresponding with the existence of Cd_2O . The curve, Fig. 23, shows a distinct break corresponding to the reduction of cadmium oxide to the suboxide. M. S. Tanatar claimed to have made **cadmium quadrantoxide**, Cd_4O , by the cautious ignition of cadmium oxalate in a stream of dry carbon dioxide. It is a green, amorphous powder, which decomposes when treated with acids or ammonia into cadmium oxide and metallic cadmium. It is slowly decomposed by water, and is stable in dry air; its sp. gr. is 8.177 to 8.207 at 19° . When the suboxide is heated to the m.p. of cadmium in a current of carbon dioxide, it is converted into a yellowish-brown powder which is a mixture of metallic cadmium and cadmium oxide. Calorimetric measurements showed that the suboxide is not a mixture of cadmium oxide and cadmium, and it was concluded that the heat of formation of the suboxide, from cadmium oxide and the metal, is 7 Cals. H. G. Denham obtained a 5 per cent. yield of cadmium suboxide, Cd_2O , by M. S. Tanatar's and by H. N. Morse and

FIG. 23.—Time-Reduction Curve of Cadmium Oxide.

H. C. Jones' methods; he obtained a heterogeneous product containing cadmium and cadmium oxide by F. Glaser's and F. J. Brislee's methods.

The white powder which is deposited in the furnace outlets smelting zinciferous copper was known to the ancients. It is an impure zinc oxide, and probably contains arsenical oxides as well; its more modern equivalent is *tutty*. Dioscorides, in his *De materia medica* of the first century, mentioned two kinds, *pompholyx* and *spodium*. The former was white and light; the latter is blacker and heavier. He said:

In the preparation and perfecting of brass, white pompholyx is made every time that the artificer sprinkles powdered cadmia upon the metal to make it more perfect. The very fine soot which rises is called pompholyx. Other pompholyx is made from cadmia by continual blowing with a bellows.

It is here probable that the zinc ore cadmia was reduced to metallic zinc which then burnt to the oxide. Hence pompholyx was Dioscorides' term for the white flowers of zinc, *flores zinci*, which he likened to wool, and which were for a time called *lana philosophica*—philosopher's wool. The flowers of zinc were collected in an apparatus, which recalls that now employed for collecting arsenic oxide. Dioscorides continued:

The furnace is constructed in a two-storied building, and there is a medium-sized aperture opening to the upper chamber; the building wall nearest the furnace is pierced with a small opening to admit the nozzle of the bellows. The building must have a fair-sized door for the artificer to pass in and out. Another small building must adjoin this in which are the bellows and the man who works them. Then the charcoal in the furnace is lighted, and the artificer continually throws bits of cadmia from the place above the furnace, whilst his assistant, who is below, throws in charcoal, until all the cadmia inside is consumed. By this means, the finest and lightest part of the stuff flies with the smoke to the upper chamber, and adheres to the walls of the roof. The substance which is thus formed has at first the appearance of bubbles on water; afterwards increasing in size, it looks like skeins of wool. The heaviest parts settle in the bottom, while some fall over and around the furnaces, and some lie on the floor of the building. This latter part is considered inferior, as it contains a lot of earth, and becomes full of dirt.

Pliny, in his *Naturalis historia* of the first century, seems somewhat confused as to the difference between the two species *pompholyx* and *spodos*; and he applied the term *cadmia* to the mineral and to the flue-dust. G. Agricola³ covers much the same ground as Dioscorides and Pliny. The product was used for medicinal purposes. Marcus Polo also described the method employed by the Persians for making pompholyx and spodos. The resemblance between the zinc oxide obtained by combustion and flakes of snow led the alchemists to term it *nix alba*; this term was mis-translated into German as *weisses Nichts*, and the latter, translated back to Latin, became *nihilum album*—e.g. I. Lawson, *Dissertatio de nihilo* (London, 1737). Flowers of zinc have also been called *tutia alexandrina*.

In 1810, A. Bruce⁴ found a native manganiferous zinc oxide, ZnO, and he called it *red oxide of zinc*. G. Rose's, P. Berthier's, and A. A. Hayes' analyses pointed in the same direction; J. D. Whitney found samples of almost pure zinc oxide at New Jersey. R. Jameson, and C. C. Leonhard called it *prismatic zinc ore*; A. Breithaupt, *red zinc ore*; F. Alger, *stirlingite*; W. Haidinger, *zinkite*; and J. D. Dana, *zincite*. Analyses have also been reported by W. P. Blake, G. H. Stone, P. Grosser, J. A. Antipoff, G. L. Gorny, F. Rinne, H. Traube, A. Sachs, and J. T. Cundall. Crystallized zinc oxide was observed as a furnace product by J. F. L. Hausmann, A. Koch, A. Lévy, A. des Cloizeaux, J. J. Porter, F. C. Weber, G. Greim, K. Busz, W. V. Vernon, W. H. Miller, M. Delesse, J. W. Mallet, R. Cowper, H. Jordan, A. Laurent and C. Holms, F. C. Calvert, C. F. Rammelsberg, G. von Rath, H. Ries, L. Blum, and G. Rose. In 1901, E. Wittich and B. Neumann found crystallized cadmium oxide, CdO, occurring as *ein neues Cadmium-mineral* in the calamine mines of Iglesias (Sardinia).

Zinc oxide is produced when the metal is heated in air; the zinc takes fire when its temp. is high enough, part remains in the crucible, and part forms clouds of

oxide; the surface of the metal should be stirred from time to time and the woolly mass removed so as to expose a fresh surface of metal. The product is rubbed up with water, and levigated to free it from adhering grains of metallic zinc. The resulting light flocculent powder forms the so-called flowers of zinc. If the temp. is not raised to the ignition point, the zinc furnishes the so-called grey suboxide, and finally the oxide. M. Rosenfeld⁵ said that the presence of magnesium or sodium favoured the combustion of the metal. Zinc sulphate, nitrate, hydroxide, or carbonate also furnishes the oxide when calcined. This furnishes what was once called *zincum oxydatum via humida paratum*—zinc oxide prepared in the wet way. The carbonate is precipitated by adding an alkali carbonate to a soln. of a soluble zinc salt and well washing and drying the product. H. Brandhorst made the oxide by heating ammonium zinc carbonate. R. de Forcrand found zinc hydroxide is almost completely decomposed at 125°, and zinc nitrate at 300° for 2 hrs. H. Schulze calcined zinc chloride or iodide in a stream of oxygen; V. Thomas found zinc iodide is converted into the oxide at ordinary temp. when exposed to nitrogen peroxide gas. C. Brunner calcined a mixture of zinc sulphate and sodium carbonate and extracted the mass with water; J. Volhard calcined zinc chloride with mercuric oxide; E. A. Parnell, and W. Hampe and C. Schnabel calcined a mixture of anhydrous zinc sulphate and carbon to about 650°. R. Alberti calcined a mixture of heptahydrated zinc sulphate with calcium or barium carbonate. G. E. Cassel extracted zinc from its complex ores with sulphurous acid under press., evaporating the soln. to dryness, and calcining the resulting zinc sulphite. When a soln. of sodium sulphate at 60° is electrolyzed between zinc electrodes with a current of 1000 amp. and 2.5 volts, zinc sulphate is formed at the anode, and this reacts with the sodium hydroxide formed at the cathode, producing zinc hydroxide. This is then washed, dried, and ignited.

G. C. Wittstein⁶ recommended distilled zinc for the preparation of *flores zinci*. H. W. F. Wackenroder, F. P. Dulk, M. Horst, M. Veltzmann, and many others have dealt with the preparation of a highly purified zinc oxide *viâ humida paratum*. Commercial zinc oxide is also known as *zinc white*—*blanc de zinc*, *zinc weiss*, *snow white*, *Chinese white*, etc. It is largely used as a white pigment, and to a less extent in glazes and enamels. For many purposes, the physical character of the granules is of prime importance. For example, the covering power of zinc white when used as a paint is much greater when prepared by the combustion process, than when prepared by the ignition of the carbonate, etc. In France, the zinc or spelter is volatilized in a retort arranged so that the vapour is oxidized in a current of air, and the zinc oxide is collected in long settling chambers provided with hopper bottoms through which the collected oxide can be removed. In Silesia, and in America, the oxidized vapour is collected into large chambers with moistened upright canvas bags which permit the passage of flue gases, but arrest the oxide of zinc. J. Thomson, J. E. Booge, etc., have described processes for the preparation of zinc oxide.

Instead of oxidizing metallic zinc, several methods have been proposed for obtaining the oxide more directly from zinc ores. S. T. Jones,⁷ for example, in 1850, and S. Wetherill, in 1855, worked with franklinite from New Jersey. The ore is conc. by magnetic separation; mixed with about half its weight of anthracite coal, and possibly limestone; and fed into a furnace. A blast of air is admitted to the furnace. The zinc is reduced to metal, volatilized, and then burnt with a dazzling white flame. The fume is drawn away by suction fans, and passes up a brick tower where the heavier and less pure particles of oxide separate out. The fume is then blown by means of fans to a cooling room, where more settling occurs. The cooled fume then passes to the bag rooms. The zinc oxide is afterwards graded according to colour and purity; bolted through silk cloth; and packed in barrels. Several other modifications of the process have been proposed. C. Kormorek recommended oxidizing the metal in a furnace like Bessemer's converter. A. O. Walker recommended the electrical precipitation of the dust of zinc oxide suspended in air.

Crystallized zinc oxide was prepared by A. C. Becquerel⁸ in yellowish needles, by melting alkali hydroxide with powdered zinc oxide in a silver crucible. A. Daubrée obtained the crystals by passing the vapour of zinc chloride over lime; G. Brügelmann, by heating zinc oxide in a slow stream of hydrogen; H. V. Regnault, by passing steam over red-hot zinc; F. Fouqué and A. M. Lévy, by passing water vapour over red-hot zinc chloride; T. Sidot, by passing oxygen over the white-hot oxide; W. Florence, by fusing the oxide in borax; A. Gorgeu, by slowly heating a mixture of alkali and zinc sulphates; by heating zinc nitrate; or by fusing equal parts of potassium and zinc fluorides, and treating the resulting product with steam; H. Moissan, by subliming the oxide in the electric arc furnace; and V. Lepiarczyk, by heating to 1300°, a mixture of zinc sulphide and ferric oxide with exclusion of air.

The testing of zinc oxide for impurities and adulterations with barytes, etc., is a subject in analytical chemistry.⁹ F. Fuchs and F. Schiff say the yellow colour is due to the presence of cadmium oxide; and they added that the blackening of zinc oxide on exposure to light is said to be due to the presence of zinc sulphide, and the blackening may be prevented by a thorough calcination. J. Cawley said the presence of magnesia hinders the blackening. W. W. Stoddart found traces of sulphate in commercial zinc oxide. F. O. Doeltz and C. A. Graumann say the carbonate in zinc oxide is derived by absorption of carbon monoxide from the air. R. Witte said pharmaceutical zinc oxide should not be made by calcining the nitrate, because, as H. N. Morse and J. White have shown, oxygen and nitrous gases are tenaciously occluded by the oxide prepared from the nitrate. T. W. Richards also noted the absorption of oxygen and nitrogen by ignited zinc oxide. Thus, a gram of zinc oxide at 660° lost 0.37 c.c. of gas; at 750°, 0.23 to 0.31 c.c.; and at 880°, 0.16 to 0.27 c.c. H. Pape removed lead oxide from zinc oxide by extraction with lime-water or milk of lime.

F. Stromeyer¹⁰ noted that **cadmium oxide**, CdO, is formed when the metal is heated in air. H. V. Regnault also observed that the oxide is formed when cadmium is heated in contact with the vapour of water; if a current of steam is passed over the heated metal, the latter volatilizes below the temp. of the reaction. P. Sabatier and J. B. Senderens found that at 300°, finely divided cadmium is gradually oxidized by nitrous oxide; the metal simultaneously volatilizes. J. A. Wilkinson obtained the oxide by the action of sodium peroxide on molten cadmium. C. Poulenc prepared the oxide by melting cadmium fluoride with alkali carbonate; E. F. Smith and P. Heyl, by heating a mixture of cadmium chloride and mercuric oxide; and J. E. Bucher, by the calcination of the oxalate. W. S. Lorimer and E. F. Smith precipitated the carbonate by adding ammonia and ammonium carbonate to a soln. of cadmium nitrate; the precipitate was thoroughly washed with cold water, dried, and then ignited. The oxide is also obtained by heating the hydroxide, nitrate, etc. G. Werther found crystals of cadmium oxide in the distillation vessel of a Silesian zinc retort. W. Florence obtained crystals by fusing the oxide with borax; and E. Wittich and B. Neumann obtained crystals of cadmium oxide as a sublimate by heating the metal in oxygen. E. Schüler, and T. Sidot prepared crystals by heating the oxide while hot in a stream of oxygen. W. Herapath also obtained crystals of the oxide by heating the metal in a stream of air, in a glass tube.

§ 9. The Properties of Zinc and Cadmium Oxides

The colour of native zinc oxide varies from dark red to blood-red which in thin plates is dark yellow; the pigment is attributed to the presence of manganese oxide as an impurity. The artificial oxide appears as a white flocculent mass which acquires a yellow tinge when the temp. is raised, but the white colour is restored on cooling. According to A. Vogel,¹ the change is not connected with either the evolution or absorption of oxygen. The yellow tint sometimes exhibited by the artificial oxide is considered to be due to the presence of foreign oxides—e.g. F. Fuchs and F. Schiff said cadmium—but E. Jensen regarded it as characteristic of the oxide prepared by precipitation and ignition. H. W. F. Wackenroder stated that the dense oxide precipitated from hot soln. and containing traces of sodium chloride or sulphate is not yellow, whereas the higher oxide precipitated from hot soln. and afterwards ignited, has a yellow tinge when cold. R. de Forcrand noted that the crystalline powder obtained by heating the nitrate to 350° has a greenish-yellow tinge. R. Schindler said that the yellow oxide loses its coloration after it has been strongly ignited on platinum. W. Herz and E. Diesel made a similar observation. J. Tafel found purified and dry colourless zinc oxide is coloured brown by strongly rubbing, by press., or by exposure to canal or cathode rays; the colour is removed by strong calcination. Cadmium oxide varies from a yellowish-brown to a brownish-red, purple-red, dark brown, or bluish-black powder. K. Bädcker oxidized the film of metal obtained in a glass discharge tube near the cathode, and found it to be orange-yellow at ordinary temp., and brown when hot. He says that under the microscope, the layer is a continuous film. According to H. Laspeyres, the crystals of zincite have a feeble **pleochroism**. R. Whytlaw-Gray and co-workers studied the aerosols or smokes of zinc and cadmium oxides.

V. Kohlschütter and J. L. Tüscher found that zinc and cadmium oxides can be obtained in a highly disperse form by vaporizing the metals in an electric arc; suddenly chilling by a current of cold air; and precipitating the fume by means of a high tension electric field. Zinc oxide, zincite, or red zinc ore forms hexagonal bipyramidal **crystals** which, according to H. Traube, have the axial ratio $a:c=1:6077$. The forms of the crystals have also been studied by J. Antipoff, G. T. Prior, H. G. F. Schröder, A. Lévy, J. Schabus, F. Rinne, G. Greim, K. Busz, G. Cesaro, A. Hutchinson, H. Ries, A. Sachs, J. F. L. Hausmann, A. des Cloizeaux, P. Grosser, and F. Sandberger. Cadmium oxide crystallizes in the cubic system;

T. Sidot's oxide is in the form of small cubes; both H. Moissan, and G. Brügelmann obtained hexahedral crystals; and A. Ditte, and E. Schüler obtained needle-like crystals or octahedral forms; C. Poulenc, brown plates; and E. Schüler, a dark bluish-black powder of microscopic octahedra. Similar forms were observed by K. von Hauer, G. Brügelmann, and B. Neumann and E. Wittich. G. Werther obtained combinations of tesseral octahedra and icositetrahedra, and of cubes and dodecahedra. W. L. Bragg showed that **X-radiograms** of zinc oxide indicate that the zinc atoms are arranged on two hexagonal space-lattices with their centres corresponding closely with those of a set of equal spheres in hexagonal close packing. The corresponding axial ratio is $a : c = 1 : 1.632$, while the observed value is $1 : 1.6077$. The positions of the atoms are identical with those of the hexagonal close-packed arrangement of spheres if the latter be supposed to contract in the direction parallel to the hexagonal axis so as to reduce the $c : a$ ratio from 1.632 to 1.6077. The oxygen atoms are probably on two hexagonal space-lattices identical with those on which the zinc atoms are situated, and derived from the latter by a movement of translation parallel to the c -axis. This brings every oxygen atom into the centre of four zinc atoms arranged at the corners of what is very nearly a regular tetrahedron. This is illustrated in Fig. 24, where the black spots indicate zinc atoms, and the circles, oxygen atoms. G. Aminoff, and W. L. Bragg computed that the elementary parallelepiped has sides $a = 3.22$ Å. and $c = 5.20$ Å. J. A. Hedvall, and G. Aminoff studied the X-radiogram of zinc oxide; and W. P. Davey and E. O. Hoffman that of cadmium oxide. W. P. Davey found that cadmium oxide exhibits the simple cube lattice with sides 4.61 Å., and the closest approach of the atoms, 2.30 Å. M. L. Huggins made observations on this subject. F. Rinne studied the **corrosion figures**; and H. Traube the **pyro-electricity** of crystals of zincite.

The reported numbers² for the **specific gravity** of zinc oxide range between R. Böttger's 5.432, and C. J. B. Karsten's 5.7344; H. G. F. Schröder's mean is 5.65. In addition, G. Brügelmann gave 5.47 at 15° for the amorphous oxide, and 5.782 at 15° for the crystalline oxide. W. P. Blake's value for zincite is 5.684; and E. Madelung and R. Fuchs', 5.5783 (0°). C. J. B. Karsten gave 6.9502 for the sp. gr. of cadmium oxide; W. Herapath, 8.183 at 16.5° ; and G. Werther, 8.1108. The **hardness** of zincite is between 4.0 and 4.5; that of cadmium oxide crystals is about 3.0. A. Reis and L. Zimmermann have discussed this subject. E. Madelung and R. Fuchs gave 0.77×10^{-6} megabars per sq. cm. for the **compressibility** of zincite.

H. Fizeau³ gave $\alpha = 0.00000316$ for the **coefficient of thermal expansion** of zinc oxide, and H. Kopp gave $\alpha = 0.000004$ for the coeff. of linear and 0.000016 for the coeff. of cubical expansion. H. V. Regnault gave 0.1248 for the **specific heat** of zinc oxide between 17° and 98° ; measurements at a low temp. were made by A. Magnus. The oxides of zinc and cadmium are highly refractory towards heat. R. Cusack gave 1260° for the **melting point** of red zinc ore. H. Pape found that the oxide sintered before it fused.

The **volatility** of zinc oxide is marked at a white heat. T. Sidot⁴ also reported the volatility of cadmium oxide at a white heat. R. de Forcrand said that no volatilization or dissociation occurs at a bright red heat; nor did A. A. Read detect any change when zinc or cadmium oxide is heated to the m.p. of platinum. H. Hasenclever and C. Stahlschmidt found that zinc oxide begins to volatilize at about 970° , and at 1054° it lost 16.9 to 17.8 per cent. in weight when heated for 30 mins.

FIG. 24.—W. L. Bragg's Space-lattice of Zinc Oxide.

in a stream of carbon monoxide. The oxide made by roasting zinc blende does not volatilize appreciably at 970° , but does so at 1054° . F. O. Doeltz and C. A. Graumann obtained rather lower values for the volatility of zinc oxide. They said that the volatilization is inappreciable at 1000° , but begins at 1200° ; at 1300° , the oxide loses about one per cent.; at 1400° , 13 per cent.; and at 1700° , the volatilization is very rapid. They added further that some reports of loss by volatilization when zinc oxide is calcined in air may be really mal-observations due to the expulsion of a little absorbed carbon dioxide; and that the oxide which has been calcined in air for an hour at 1000° , loses 0.06 to 0.09 per cent. when recalined for 2 hrs. at the same temp.; and the oxide which has been calcined four times at 1000° , loses 0.14 to 0.18 per cent. when again calcined at 1200° for 2 hrs. O. L. Kowalke reported that zinc oxide may be completely volatilized between 1370° and 1400° . F. O. Doeltz and C. A. Graumann noted that cadmium oxide volatilizes below 1000° . J. C. G. de Marignac, and A. Erdmann observed that when zinc oxide is heated in a platinum crucible by a gas-flame, a film is formed on the inside, and the former assumed that the zinc oxide is dissociated and that the zinc alloys with the platinum; but H. N. Morse and W. M. Burton said that reducing gases pass through the metal crucible and by reducing the oxide liberate the metal, which then alloys with the platinum. H. St. C. Deville and L. Troost sublimed zinc oxide in a stream of hydrogen, and concluded that the oxide is first reduced by the hydrogen, forming water, and that the metal is then oxidized by the water, reforming the oxide. No sublimation occurred in a stream of inert gas. H. N. Morse and J. White at first attributed the apparent volatilization to alternate reduction and oxidation of zinc oxide when heated in a stream of hydrogen. They found the oxide does not sublime when heated in vacuo, but it does so when heated with zinc. Later, they attributed the apparent volatilization of zinc oxide from a mixture of the metal and the oxide to the mechanical transport of particles of the oxide with the zinc vapour, for they found that powdered porcelain, or barium carbonate, is similarly transported without change of composition. Similar remarks apply to cadmium oxide. H. Moissan obtained a sublimate of needle-like crystals of the oxide in the electric-arc furnace. C. Zenghelis claimed to have obtained evidence of the volatilization of zinc oxide at ordinary temp. W. Stahl estimated the **dissociation pressure**, p atm., of zinc oxide to be:

	1227°	1227°	1727°	2227°	2727°	3227°	3427°	3527°	3627°
p	0.0 ₆₆ 1333	0.0 ₁₆ 3620	0.0 ₁₀ 9489	0.0 ₆ 7358	0.0 ₃ 3057	0.02365	0.09784	0.1885	0.3517

and the dissociation press. of the oxide is equal to the partial press. of atm. oxygen at 3544° . According to A. Colson, cadmium oxide dissociates below 600° , and the volatilized film of cadmium forms in transmitted light a violet-blue film on the walls of the glass vessel.

J. Thomsen⁵ gave the **heat of formation** of zinc oxide (Zn, O) as 85.43 Cals.; C. M. Despretz, 85.00 Cals.; M. Berthelot, 85.40 Cals.; P. L. Dulong, 84.408 Cals.; T. Andrews, 86.90 Cals.; P. A. Favre and J. T. Silbermann, 84.50 Cals.; T. Woods, 85.50 Cals.; and M. Délepine and L. A. Hallopeau, 84.80 Cals. R. de Forcrand gave for the heat of formation of zinc oxide, prepared from the nitrate at 125° , 82.97 Cals.; and prepared from the nitrate at 350° , 83.00 Cals. A. Ditte also found different values for the heat of formation of the oxide which has been calcined at different temp., as shown by the heat of soln. in dil. sulphuric acid, but J. C. G. de Marignac failed to confirm this observation. The results per gram of zinc oxide, calcined at:

	J. C. G. de Marignac.				A. Ditte.	
350°	244.2	cals.
Dull redness	272.0	"
Bright redness	299.3	"

R. de Forcrand gave for the heat of soln. in dil. sulphuric acid, 25.24 Cals. for zinc oxide obtained by calcining the hydroxide at 125° ; 25.21 Cals., by calcining the

nitrate at 350°; 23·91 Cals., by calcining at bright redness the precipitated hydroxide; and 23·51 Cals., by the combustion of zinc. Precipitated zinc hydroxide has a heat of soln. in dil. hydrochloric acid of 20·23 Cals. A. Ditte also found that the heat developed in the soln. of a gram of cadmium oxide, obtained by calcining the nitrate, in dil. sulphuric acid, containing 382·5 grms. H_2SO_4 per litre, is 229·6 cal., or 14·238 cal. per eq.; while the heat developed from the oxide obtained by the combustion of cadmium, or the calcination of the carbonate, is 234·1 cal. per gram, or 14·513 cal. per eq. W. Herz was unable to establish the existence of allotropic forms of zinc oxide. G. Bodländer calculated the free energy of the reaction $\text{Zn} + \frac{1}{2}\text{O}_2 = \text{ZnO}$ to be $85800 - 30·8T + 2·29T \log p$ cal. per mol, where p is the press. of the oxygen in the atm. M. Berthelot gave 66·4 Cals. for the heat of formation of cadmium oxide; J. Thomsen, 65·78 Cals.; and W. Müller-Erbach gave 65·6 Cals. A. Ditte gave (Cd, O), 60·8 Cals., and for the transformation of amorphous into crystalline cadmium oxide, 0·540 Cal. R. de Forcrand, and N. von Klobukoff also measured the thermal effect in passing from the amorphous to the crystalline state. J. Thomsen found for the **heat of neutralization** of zinc hydroxide $\text{Zn}(\text{OH})_2 + \text{H}_2\text{SO}_4$ aq., 23·41 Cals.; $\text{Zn}(\text{OH})_2 + 2\text{HNO}_3$ aq., 19·83 Cals.; $\text{Zn}(\text{OH})_2 + 2\text{HCl}$ aq., 19·83 Cals.; and $\text{Zn}(\text{OH})_2 + 2\text{CH}_3\text{COOH}$ aq., 18·03 Cals. A. Ditte, and M. Berthelot measured the heat of neutralization of cadmium oxide in dil. sulphuric acid; and J. Thomsen found $[\text{Zn}, \text{O}, \text{H}_2\text{SO}_4 \text{ aq.}] = 106·09$ Cals. J. Thomsen gave for the heat of neutralization $[\text{Cd}(\text{OH})_2, 2\text{HCl}, \text{H}_2\text{O}]$, 20·29 Cals.; $[\text{Cd}(\text{OH})_2, 2\text{HBr}, \text{H}_2\text{O}]$, 21·56 Cals.; and $[\text{Cd}(\text{OH})_2, 2\text{HI}, \text{H}_2\text{O}]$, 24·21 Cals.; $[\text{Zn}, \text{O}, 2\text{HNO}_3, \text{aq.}]$, 102·51 Cals. The **heat of hydration** of zinc oxide, according to J. Thomsen, is $[\text{Zn}, \text{O}, \text{H}_2\text{O}]$, 82·68 Cals.; $[\text{ZnO}, \text{H}_2\text{O}]$, -2·75 Cals.; and for cadmium oxide $[\text{Cd}, \text{O}, \text{H}_2\text{O}]$, 65·68 Cals., or $[\text{CdO}, \text{H}_2\text{O}]$, -0·10 Cal.

According to A. des Cloizeaux,⁶ the crystals of zincite have a positive **double refraction**, and the subject has been investigated by G. Cesaro, A. Breithaupt, and A. Madelung. W. W. Coblentz⁷ found that zincite had a poor reflecting power, and the selective reflection **spectrum** exhibited no bands; he also examined the **emission spectrum** of the heated oxide, and found a uniform distribution of energy in the infra-red, with a depression in the emissivity wave-length curve at $3·2\mu$. Zinc oxide emits an intense light when heated in the blowpipe flame. T. Drummond found that if used in place of lime for the limelight, the intensity of the light was less than that of magnesia, and the oxide rapidly wasted away. The **thermo-luminescence** of zinc oxide above 880° has been studied by E. L. Nichols and B. W. Snow. E. L. Nichols and D. T. Wilber found that, like calcium oxide, zinc oxide exhibits **flame luminescence**. E. L. Nichols showed that pure zinc oxide does not exhibit photo-luminescence, nor is it excited by X-rays; but it is luminescent above red heat—a red band appearing at about 568°, and at 700° this is displaced by a yellowish-green band which disappears about 940°. Cadmium oxide gave no flame phosphorescence. According to E. L. Nichols, at 1000°, in the oxyhydrogen flame, zinc oxide appears blue, not red. According to W. Wien, zinc oxide gradually loses its fluorescent qualities in the **canal rays**, and at the same time acquires a yellow colour, and, according to J. Tafel, is denser. According to H. Jackson, the fluorescence of purified zinc oxide also occurs under the influence of the **cathode rays**. J. Ewles found the minimum voltage for the excitation of the cathodo-luminescence to range from 400 to 850 with different samples of zinc oxide. The rays of radioactive bismuth—polonium—were found to give an intense phosphorescence with zinc oxide. According to W. Wien, the canal ray fluorescence is not exhibited by zinc oxide prepared from the hydroxide precipitated with sodium carbonate. J. A. Wilkinson examined the luminescence of cadmium oxide, and cadmium salts. E. Wiedemann and G. C. Schmidt also found the intensity of the luminescence to be dependent on the acid radicle. G. C. Schmidt attributes the yellow or yellowish-green **fluorescence** of zinc oxide to traces of cadmium; when the latter is removed by fractional distillation, the oxide does not fluoresce. E. Goldstein found the presence of 0·0000001 part of foreign metal to be effective in the production of the

cathodic luminescence. When zinc oxide preparations are illuminated with **ultra-violet rays**, a luminescence is displayed which increases to a maximum, and on removing the exciting rays, the luminescence disappears, but a weak and transient phosphorescence appears. The wave-length of the luminescence is in the region 300–313 μ . A. Karl found that a calcined mixture of zinc oxide with silicic, stannic, titanous, or zirconium oxide, praseodymium oxide, manganese nitrate, silicate, stannate, titanate, or zirconate readily shows **tribo-luminescence**, giving a glow visible in daylight, when rubbed with a metal or glass rod. It is assumed that solid soln. are formed. Manganiferous zinc sulphate or nitrate is also triboluminescent. According to G. C. Schmidt, a solid soln. of cadmium and zinc oxide is not formed by the combustion of cadmiferous zinc, but is formed when the mixture is calcined; and the luminescence is said to be connected with the decomposition of the salt or oxide. According to H. Maraoka and M. Kasuya, zinc or cadmium oxide blackens a **photographic plate**. C. Winther found that some varieties of zinc oxide act as optical sensitizers in a number of processes without being changed—e.g. white lead and glycerol mixtures do not turn black in daylight or in the electric arc, but they blacken if zinc oxide is present; and oxygen is converted to ozone, provided zinc oxide be present, when exposed through glass to light from a quartz mercury lamp.

According to F. Beijerinck,⁸ and O. Frölich, zincite is an electrical conductor, and its **electrical conductivity** is greater perpendicular to the principal axis than it is parallel to that axis. J. Sohlmann noted the relatively high conductivity of zinc oxide when it is heated by the oxy-hydrogen flame, or by the electric arc; and below 1000° it begins to conduct better than the oxides of calcium, beryllium, or magnesium. M. Lapschin and M. Tichanowitsch reduced zinc oxide to the metal by a battery of 60 to 370 Bunsen's cells. C. A. Kraus found the sp. conductivity of cadmium oxide to be 0.083×10^{-4} mho. A. A. Sommerville found that a column of zinc oxide, 1 cm. diameter and 10 cms. long, had an **electrical resistance** of 10⁷ ohms at 393°, and 72 ohms at 1100°. The electrical conductivity of zinc oxide was found by F. Skaupy to be greater in vacuo than in air. With a direct current of 110 volts, at a press. of 0.01 mm. of mercury, 2–3 milliamps. passed through the oxide, but in a few seconds this increased to 100–500 milliamps. There was no evolution of oxygen. F. Skaupy suggested the use of zinc oxide for a resistance with a negative temp. coeff., and for non-corrosive electrodes in vacuum tubes. F. Streintz found that the conductivity of the strongly compressed powder of cadmium oxide does not change one per cent. when kept 14 days. Increasing the press. or lowering the temp. down to that of liquid air, has no influence on the conductivity. The specific resistance amounts to 280×10^{-4} ohms. A rod 2.3 cms. long and 0.229 cm. diameter has a resistance of 1.2 ohm between –180° and 200°; above 200°, the resistance decreases rapidly so that at 300° it is 0.26 ohm, and at 400°, 0.11 ohm; and when cooled to the temp. of the room, the resistance is only 0.06 ohm. The resistance, R , changes with the temp. θ° , so that $R = 0.0055(1 + 0.001\theta)$. F. Streintz assumes that above 200°, a poor conducting variety of cadmium oxide changes into a good conductor. S. Veil found that the curve showing the variation in the conductivity of cadmium oxide with temp. has three points of inflexion which are assumed to represent α -, β -, and γ -allotropic forms of the oxide. K. Bädcker measured the conductivity of films of cadmium oxide on glass; and he found the **thermo-electromotive force** of copper or silver against cadmium oxide is 30.0 microvolts per degree between 18° and 100°, and 40.0 microvolts between 100° and 180°.

Zinc oxide was observed by J. Perrin to be feebly positive in neutral water, and strongly positive in acidified water. R. Lorenz found the potential of zinc in contact with oxygen, against a normal hydrogen electrode in neutral soln. to be –0.31 volt. L. Bloch measured the **contact difference of potential** of zinc oxide against distilled water = 1 volt; against $N-H_2SO_4$, or $N-HCl$, 1.2 volt, and with more dil. soln., the potential decreases; the difference of potential against alkaline soln. is smaller than for water, and against salt soln. the value is nearly the same as for water.

R. Lorenz and H. Hauser found the e.m.f. of the cell $\text{Cd}|\text{O}_2, N\text{-NaOH}, \text{H}_2|\text{Pt}$ to be 0.411 volt at 18.4° , and 0.308 volt at 30° ; while the e.m.f. of the cell $\text{CdO}|\text{O}_2, N\text{-Na}_2\text{SO}_4, \text{H}_2|\text{Pt}$ is 0.069 volt. S. Glixelli studied the **electro-osmosis** of zinc oxide. S. Meyer found the **magnetic susceptibility** of powdered zinc oxide to be -0.26×10^{-6} units at 16° (air unity); C. Chéneveau gave -0.33×10^{-6} units. E. Thomson⁹ has investigated the orientation of fine particles of zinc and cadmium oxides in the magnetic field.

T. W. Richards and E. F. Rogers¹⁰ have shown that zinc oxide prepared by the ignition of the nitrate always carries **occluded gases**, -1.0 to 15 c.c. of gas per 10 grms. of oxide; the gas consisted mainly of **oxygen** and **nitrogen** with a trace of carbon dioxide. The oxide derived from the carbonate contained rather more carbon dioxide. Cadmium oxide contained only a trace of occluded gas. H. N. Morse and H. B. Arbuckle obtained oxygen and nitrogen from ignited zinc and cadmium oxides. C. M. Despretz,¹¹ and H. W. F. Wackenroder observed the great difficulty in reducing zinc oxide by **hydrogen**. H. St. C. Deville showed that with a slow current of gas and a wide porcelain tube, crystalline zinc oxide is alone produced, but with a fast current of gas and a narrow porcelain tube, the oxide is reduced. He assumed that reduction probably occurs in both cases, and he considered that the effect is not due to mass action. He said:

At the moment when the steam and zinc react to reproduce zinc oxide, and hydrogen, the latter gas, by reason of its mass, should protect the metal from oxidation. This never happens if the operation is conducted with sufficient slowness. All is explained, however, by admitting that a variation of temp. causes the affinities to be reversed. Thus, in the part of the tube heated directly, zinc vapour and steam may coexist; but in the parts less heated, where the zinciferous deposit occurs, the affinities change, water is decomposed, and every trace of metallic zinc disappears. This takes place in my experiments; but when the hydrogen passes with rapidity, the zone of the tube in which the reverse action occurs is traversed by the mixture of vapours with such rapidity that the cooling prevents the reversal of the reaction.

H. St. C. Deville's experiments were confirmed by J. Percy, and it is more probable that the reversible reaction: $\text{ZnO} + \text{H}_2 \rightleftharpoons \text{H}_2\text{O} + \text{Zn}$, is involved in both cases, and that with a fast current of hydrogen the zinc vapour is carried along and condensed before the reverse reaction has time to progress very far. According to F. Glaser, hydrogen reacts slowly with zinc oxide at 454° ; and after heating for an hour at 600° , 1.25 per cent. of metal is volatilized, and after heating for another hour at 670° , about half the metal had sublimed. W. Kumpmann stated the reduction of zinc oxide by hydrogen begins at about 465° , and no metal or suboxide is produced with a slow current of gas at from 700° to 1000° . The more rapid the current of gas the more zinc oxide sublimes, and some metal may be obtained as a fine dust at 500° or even lower. F. Glaser found that the reaction between hydrogen and cadmium oxide begins at about 282° and the reduction is complete in 3 hrs. between 290° and 300° . W. Müller found the reduction of cadmium oxide by hydrogen begins between 250° and 260° , and is quite fast at 270° ; accordingly he recommended this reaction as a means of separating cadmium and copper oxides; and L. C. Barreswil, as a means of separating zinc and cadmium oxides; R. E. Wilson and T. Fuwa studied the hygroscopicity of zinc oxide.

According to H. Moissan,¹² **fluorine** does not attack cold zinc oxide, but near 500° decomposition takes place; and C. Poulenc found that **hydrogen fluoride** forms cadmium fluoride when passed over red-hot cadmium oxide. R. Weber obtained zinc or cadmium chloride and oxygen by passing **chlorine** over the red-hot oxide. Zincite is readily soluble in dil. **acids**—dil. hydrochloric, sulphuric, acetic, and nitric acids. These acids also dissolve cadmium oxide. G. J. Fowler and J. Grant observed that zinc oxide has no effect on the decomposition of **potassium chlorate** by heat. H. Brandhorst found zinc oxide to be soluble in molten zinc or magnesium chloride. W. Bersch studied the action of cadmium oxide on soln. of the **chlorides, bromides, and iodides of the alkalies and alkaline earths**.

Zinc oxide is decomposed by the vapour of **sulphur** forming zinc sulphide and

sulphur dioxide. E. Aston and L. Newton,¹³ contrary to C. R. Fresenius, were unable to convert zinc oxide quantitatively into zinc sulphide by admixture with sulphur, and heating in a current of hydrogen—from 5 to 15 per cent. escaped conversion—even after repeated treatments. J. B. Senderens found zinc oxide is not affected by boiling it with water and sulphur, while cadmium oxide forms the sulphide, sulphate, and a little thiosulphate. H. Moissan observed that a soln. of **ammonium sulphide** converts zinc oxide into orange-yellow crystals. H. Schiff detected no action between **sulphur dioxide** and zinc oxide or zinc sulphide; and E. Prioznik found that at ordinary temp. a soln. of ammonium polysulphide converts cadmium oxide completely into the sulphide. C. Matignon and F. Bourion found the vapour of **sulphur chloride**, S_2Cl_2 , passed with a stream of chlorine over red-hot zinc oxide, produced zinc chloride. F. Faktor fused zinc oxide with **sodium thio-sulphate**, and found that sulphur dioxide is evolved, and zinc sulphide formed. V. Lepiarczyk reported that when a mixture of zinc oxide, carbon, and **calcium sulphate** is heated to about 1300° , zinc sulphide is formed; W. Mostowitsch obtained a similar result with **barium sulphate** at about 800° . The action of **sulphuric acid** on cadmium and zinc oxides has been previously indicated. P. Sabatier found zinc oxide reacts vigorously with **nitrosyldisulphonic acid**, $NO(HSO_3)_2$, forming zinc sulphate.

C. H. Burgess and A. Holt¹⁴ found zinc and cadmium oxides dissolve to a clear glass in molten **boric oxide**. J. Percy likewise found zinc oxide dissolves in fused boric acid in the proportions $ZnO : B_2O_3$, 1 : 1, 2 : 1, 3 : 1, and 4 : 1, forming transparent glasses; and with a mixture of zinc oxide and **alumina**, at a high temp., he obtained a "compact, grey, strong substance which scratched flint glass"—*vide* the aluminates. When cadmium oxide is heated with **phosphorus**, B. Renault found that cadmium phosphide is formed. H. Hvorslef likewise obtained zinc phosphide by the action of phosphorus vapour on zinc oxide. F. Ephraim heated cadmium oxide with **sodium amide** in a sealed glass tube, and obtained beads of cadmium.

When a mixture of zinc oxide and **carbon** is heated to a bright redness, zinc vapour and carbon monoxide are produced; and if the zinc oxide is in excess, carbon dioxide is also formed—*vide* the extraction of zinc. O. Boudouard,¹⁵ and W. Mostowitsch detected signs of the reduction of zinc oxide by carbon at 800° , and F. O. Doeltz and C. A. Graumann between 800° and 1000° . W. Kumpmann found the reduction commences at a temp. over 1000° . W. McA. Johnson gave 1022° with wood charcoal, and 1029° with coke; E. Prost gave 1075° . M. Bodenstein and F. Schubart found the velocity, v , of the reaction between zinc oxide and carbon at different temp., measured in terms of loss in weight per gram per min. to be:

		990°	1000°	1016°	1030°	1039°
v	:	0.050	0.058	0.156	0.180	0.180
$dv/d\theta$:		0.0008	0.0061	0.0017	0.0000

According to O. Boudouard, the evolution of gas which commences at 800° , ceases as the temp. rises, and again commences at about 1100° , and between 1125° and 1150° , there is a regular stream of gas which contains about 99 per cent. carbon monoxide and 1 per cent. of carbon dioxide. Zinc oxide prepared artificially is more easily reduced than that obtained by roasting the sulphide. K. Eichhorn, F. Fischer, and W. Hempel have studied the reduction of zinc oxide by carbon; the latter said the reaction starts below the b.p. of zinc, and is complete between a bright red and a white heat. According to R. C. Schüpphaus, the reduction of zinc oxide by carbon commences at 910° , and when the press. is maintained above the calculated press. of zinc vapour, at 1150° , liquid zinc collects as an ingot at the bottom of the crucible, although the temp. is higher than the b.p. of zinc under atm. press. A stable canary-yellow oxide is produced which contains more zinc than corresponds with the normal oxide, and which may be a suboxide (*q.v.*). F. O. Doeltz and C. A. Graumann found that the reduction of cadmium oxide by sugar carbon is very slow

between 530° and 620°—relatively 0.1 per cent. loss of weight was observed; there was an abrupt acceleration as the temp. rose in the vicinity of 700°, and relatively 1.0 per cent. loss of weight occurred.

Zinc is directly extracted nearly always from a mixture of zinc oxide and some form of carbon. The two are often in the form of coarse particles and but imperfectly mixed. Contact between the solids is therefore imperfect, and yet the reduction is virtually complete. Hence, argued F. le Play, **carbon monoxide** alone must be the reducing agent; he extended the hypothesis and assumed that solid carbon does not reduce oxides by direct contact. While admitting that carbon monoxide can reduce the oxides of the metals, J. L. Gay Lussac pointed out that it does not follow that solid carbon is incapable of reducing oxides by direct contact. The more easily reducible oxides—silver, mercury, copper, lead, bismuth, etc.—are reduced by carbon monoxide forming carbon dioxide. There are also oxides—manganese, chromium, cerium, titanium, and potassium—which resist the action of carbon monoxide, and are yet reducible by carbon. F. Clément and J. B. Désormes, P. L. Dulong, C. M. Despretz, and A. Müller early noted the difficulty in reducing zinc oxide with carbon monoxide, and I. L. Bell reported that zinc oxide is not changed when heated with carbon monoxide in a sealed tube. According to W. Kumpmann, similar remarks apply to carbon monoxide as were made with respect to the action of hydrogen on heated zinc oxide. F. O. Doeltz and C. A. Graumann found the reaction begins between 800° and 1000°; W. Kumpmann obtained signs of the beginning of the reaction at 465°; and it is appreciable between 700° and 800°. The relations between carbon monoxide and dioxide, zinc, and zinc oxide have been indicated in connection with the extraction of zinc. The reversible reaction is symbolized: $\text{ZnO} + \text{CO} \rightleftharpoons \text{CO}_2 + \text{Zn}$; the carbon dioxide produced in the action of carbon on zinc oxide has no chance to reoxidize the zinc because, in the presence of excess of carbon, it is reduced to carbon monoxide, so that as long as sufficient red-hot carbon is present, zinc and carbon monoxide are the sole products of the reactions. W. Kumpmann found that zinc oxide sublimed unchanged in a mixture of 90 vols. of **carbon dioxide** and 10 of carbon monoxide; and from a mixture of carbon and zinc oxide in a stream of carbon dioxide at 700°; or a stream of steam at 800°. Zinc oxide attracts carbon dioxide from the air; brown cadmium oxide behaves similarly and becomes white.

A. Mailhe¹⁶ found zinc oxide decomposes methyl alcohol into equal parts of hydrogen and carbon monoxide. W. Ipatjeff, and P. Sabatier and A. Mailhe found ethyl alcohol vapour is decomposed by zinc oxide; some aldehyde is formed; and at 340°–350°, a gas with 95 per cent. hydrogen and 5 per cent. of ethylene is produced. A. Mailhe found fatty acid vapours form ketones and carbon dioxide at about 400°; thus, at 430°, acetic acid forms acetone. Analogous results were obtained with cadmium oxide. W. G. Palmer studied the catalytic action of zinc oxide admixed with cupric oxide on the dehydrogenation of ethyl alcohol.

F. von Kügelgen¹⁷ reduced red-hot zinc oxide by **calcium carbide**. P. Berthier, and J. Percy fused zinc oxide with **alkali carbonate** and obtained a liquid which congealed to a colourless, translucent, crystalline mass; fused **potassium cyanide** dissolves zinc oxide without showing any signs of the vaporization of reduced zinc. W. Bersch investigated the action of soln. of the alkali and alkaline earth **thiocyanates** on cadmium oxide; and J. Milbauer found that zinc oxide is converted into amorphous zinc sulphide by potassium thiocyanate at about 220°; similar results were obtained with cadmium oxide. J. Percy found mixtures of zinc oxide and **silica** $\text{ZnO} : \text{SiO}_2$, in the proportions 1 : 1, 2 : 1, 3 : 1, and 4 : 1 sintered together after five hours at a white heat—*vide* the silicates. G. Rauter found **silicon tetrachloride** is decomposed by zinc or cadmium oxide between 290° and 300°.

Zinc oxide is reduced by less easily reducible metals—*e.g.* by **potassium** at a gentle heat; A. Burger¹⁸ reduced zinc and cadmium oxides by **manganese**; A. Stavenhagen and E. Schuchard, by heating with **aluminium**; and J. Percy, by heating with **iron** at a high temp. when all the zinc is volatilized. Zinc oxide has

strongly basic properties, but it is amphoteric, for it unites with other bases—to form salts—**zincates** (*q.v.*)—in which the zinc oxide appears to function as an acid radicle. According to S. Meunier, when cadmium oxide is fused with potassium or sodium hydroxide, double cadmium and alkali oxides are formed. By fusing zinc oxide with eight times its weight of **lead monoxide**, J. Percy obtained a mobile liquid which crystallizes like litharge. According to G. Tammann, zinc oxide immersed in a soln. of **silver nitrate** or sulphate remains white in diffused light, but in sunlight it is rapidly blackened; and, when the zinc oxide is removed with acetic acid, silver oxide, Ag_2O , remains. The rate of the reaction depends on the physical condition of the oxide. The reaction was studied by V. Kohlschütter and A. d'Almendra. It occurs with other basic oxides, but not with acidic oxides.

H. W. F. Wackenroder¹⁹ showed that ignited zinc oxide does not unite directly with **water** to form the hydroxide. According to A. Dupré and M. Bialas, a litre of water dissolves from 0.0042 to 0.0046 part of zinc oxide at 18°. According to F. Kunschert, soln. of zinc oxide in **alkali hydroxides** have ions ZnO_2'' , HZnO_2' , and OH' , and the difference of potential of zinc against an alkali zincate soln. relative to the normal hydrogen electrode is $1.130 - 0.029 \log C/[\text{OH}]^5$, where C denotes the conc. of the zincate; and the bracketed symbol, the conc. of the hydroxyl ions in mols per litre. F. Förster and O. Günther found 100 c.c. of a 20 per cent. soln. of sodium hydroxide dissolves in a few hours, calcined zinc oxide eq. to 2.97 grms. of zinc; precipitated zinc oxide is more rapidly dissolved—*vide* zincates. L. Rolla and R. Salani measured the decomposition tension of mixtures of fused sodium hydroxide and zinc oxide or cadmium oxide. F. Stromeyer found cadmium oxide is readily soluble in aq. ammonia. Calcined zinc oxide is also dissolved by aq. ammonia, but only in the presence of ammonium salts. According to H. Brandhorst, roasted blende is not completely soluble in ammonium carbonate soln., possibly because of the formation of zinc ferrite during the roasting. According to G. Rigg, the solubility of zinc oxide in **ammonium carbonate** soln. reaches a maximum with a definite conc. of carbon dioxide. Expressing the results in kgrms. per 10 litres of soln. with 1.2 kgrms. of NH_3 , then with a conc. C of carbon dioxide,

C	.	.	0.60	0.65	0.80	0.90	0.95	1.10	1.15	1.30	1.35	1.50
ZnO	.	.	1.15	1.37	1.54	1.60	1.73	1.90	1.86	1.74	1.54	1.43

H. Brandhorst obtained a precipitate of ammonium zinc carbonate (*q.v.*) by boiling the soln. These soln. have been studied by H. Wächter, O. Kühling, and C. R. C. Tichborne. The data with cadmium oxide are not consistent. F. Stromeyer said that the precipitate is not soluble in aq. soln. of ammonium carbonate; J. F. John, and W. Herapath said it is slightly soluble; and E. D. Clarke said it is very soluble in that menstruum. F. de Lassone found that zinc oxide is dissolved by potash-lye, **lime-water**, and aq. **ammonia**. Zinc oxide is dissolved by a soln. of **ferric chloride** or **ferric sulphate**, and eq. amount of ferric hydroxide is precipitated. According to M. Prud'homme and F. Binder, zinc chromate is produced when zinc hydroxide is treated with **potassium dichromate**. L. Kahlenberg and H. W. Hillger found zinc oxide to be soluble in a boiling soln. of **potassium tartrate**. According to A. Naumann, zinc oxide is insoluble in **acetone**.

Zinc oxide mixed with oil dries to a hard film, basic lead carbonate or white-lead dries to a much softer and more chalk-like surface. Just as zinc added to certain metals gives hardness to the resulting alloy, so, by analogy, zinc oxide added to white-lead produces a pigment which when mixed with oil and applied as a paint gives a harder and more durable surface than the white-lead alone.

P. Drinker²⁰ has given a review of the bibliography of the toxicity of zinc oxide, and of the conditions under which zinc oxide produces brass-founders' ague are discussed. Ordinary zinc oxide dust as produced, for example, in packing zinc oxide pigments does not produce the ague, whereas that produced by the burning of zinc does. It is suggested that the oxide in the first case has been flocculated

by adsorption of moisture, and is therefore deposited on the walls of the nasal passage or trachea and does not reach the lungs, whereas in the second case the oxide is in a highly dispersed state as a very fine dry powder which readily passes into the lungs, where the particles offer the maximum surface for phagocytosis and ultimate soln. In the second case, zinc is found both in the urine and the faeces, whereas in the first case practically none is found in the urine, showing that very little zinc has been dissolved.

§ 10. The Hydroxides and Peroxides of Zinc and Cadmium

R. Schindler¹ observed that when zinc in contact with iron is immersed in aq. ammonia, hydrogen is evolved, and in about 8 days, there are deposited on the zinc, and on the sides of the glass vessel, small, transparent, colourless, rhombic prisms of zinc hydroxide, $\text{Zn}(\text{OH})_2$. F. F. Runge, A. Cornu, H. Euler and R. de Forcrand prepared the crystals in a similar manner. J. Nicklès also employed the method for crystals of cadmium hydroxide. H. Euler prepared hydroxides, by precipitation from the nitrate, which appeared to have a varying solubility in ammonia. F. Goudriaan found that the precipitate obtained by adding ammonia to a soln. of zinc nitrate or chloride immediately becomes more gritty, heavier, and less gelatinous when washed a few times with boiling water. When dried at 100° , the product contained 0.6 per cent. water. The solubility in sodium hydroxide also decreases when the hydroxide is kept for a longer time. O. Klein distinguished three forms of the hydroxide. If a soln. of zinc sulphate is allowed to drop into one of potassium hydroxide until the white precipitate just fails to redissolve, the soln. is sat. with respect to the modification *A*. In time this soln. deposits a modification *B*, which often forms regular crystals. If collected and dried, *B* passes into a still less soluble modification *C*. The solubility of all three modifications in soln. of different conc. has been determined. *A* has the composition $\text{H}_2\text{Zn}_2\text{O}_3$, *B* and *C* have the composition $\text{Zn}(\text{OH})_2$. F. Goudriaan showed that amorphous gelatinous zinc hydroxide is a phase with a varying proportion of water, the proportion of water depends on the mode of preparation, the age, etc. The amorphous product is not stable at 100° , but is rather in a metastable state with a tendency to stabilization to ZnO . The crystalline hydroxide can be obtained as a phase of constant composition:

To 50 c.c. of *N*-KOH add *N*- ZnSO_4 from a burette until the hydroxide first formed has redissolved, and a point is reached at which the liquid remains slightly turbid when shaken. When vigorously shaken, or when the glass wall is scratched, and the soln. allowed to stand for a few minutes, a heavy sandy precipitate is formed. Seeding with crystals previously obtained accelerates the crystallization. Under the microscope, the powder consists of small elongated bar-shaped crystals. They filter easily, and, unlike the amorphous product, they can be readily cleaned by washing. The crystals dried at 40° – 50° have the composition $\text{Zn}(\text{OH})_2$.

A. C. Becquerel obtained crystals of zinc hydroxide by placing a rod of zinc, wound

with copper wire, in a soln. of silicic acid in caustic lye. He assigned the formula $\text{Zn}(\text{OH})_2$ to the regular octahedrons so obtained. Colloidal zinc hydroxide is obtained by treating a soln. of zinc nitrate with insufficient potassium hydroxide for complete precipitation, and washing the product; if an excess of the alkali is used, or if a soln. of zinc chloride or sulphate is employed, the product is not nearly so pure. W. Herz, A. Hantzsch, B. B. Kuriloff, and R. Lorenz employed a similar process. They commented on the difficulty in separating the adsorbed alkali hydroxide, and showed that some sulphate is also retained very tenaciously—possibly as basic sulphate. V. T. Hall commented on the adsorption of chlorides by the precipitated hydroxide, and F. Goudriaan showed that the nitrate is likewise adsorbed by the precipitate. C. E. Linebarger showed that the amount of alkali required for the reaction is dependent on the conc. and temp. of the soln. J. Lefort and P. Thibault showed that the presence of gum hinders the precipitation. S. E. Linder and H. Picton prepared the hydroxide as a transparent gelatinous mass. F. Stromeyer likewise prepared cadmium hydroxide by adding potassium hydroxide to a soln. of a cadmium salt; and by treating cadmium oxide with a soln. of potassium hydroxide. W. Bonsdorff recommended precipitating a soln. of cadmium nitrate with sodium hydroxide free from carbon dioxide for cadmium hydroxide; and L. Schaffner used potassium hydroxide as precipitant, and recommended dil. soln. O. Follenius found tartaric acid hinders the precipitation in the cold; sugar hinders it when hot; while citric, malic, succinic, and benzoic acids have no influence. Silver oxide was found by D. Vitali to precipitate partially the cadmium as hydroxide from soln. of cadmium sulphate. W. Vaubel added ammonia to a soln. of zinc salt until it reacted neutral with litmus and reddened with phenolphthalein, and boiled the soln. The presence of ammonium salts hindered the precipitation. A. Vogel and C. Reischauer mixed a soln. of zinc nitrate with an excess of ammonia, and introduced a piece of zinc into the liquid; crystals of the hydroxide were gradually formed and a gas was evolved. F. J. Malaguti, M. Sarzeaud, J. Ville, and A. Cornu prepared crystals of zinc hydroxide more rapidly by the slow electrolysis of an ammoniacal soln. of zinc oxide. The yield is better if finely powdered zinc carbonate be added to the electrolyte. P. Meyer electrolyzed a very dil. soln. of hydrogen peroxide with a zinc anode, and an inert cathode; R. Lorenz electrolyzed an alkali salt with zinc anode, or a cadmium salt with a cadmium anode, and platinum cathodes; O. and H. Strecker electrolyzed soln. of sodium chloride or chlorate with a cadmium anode; and E. Leriche electrolyzed a soln. of sodium chloride with a zinc anode and an iron cathode. M. Malzac treated zinc blende with aq. ammonia, exposed to air.

D. Lance obtained the hydroxides directly from the ores by treatment with aq. ammonia or an amine or a mixture of these. The hydroxides are fractionally precipitated by heat in the order: zinc, cadmium, cobalt, nickel, copper, and silver. According to G. Buchner, crystalline cadmium hydroxide is obtained by heating a soln. of 10 grms. of cadmium iodide in 150 c.c. of water; 360 grms. of potassium hydroxide and 13 grms. of water were then added with continuous stirring at 135° until all the hydroxide had dissolved. After 12 hrs., the soln. was diluted with water, and plates of cadmium hydroxide with a mother-of-pearl lustre were produced. A. de Schulten treated a soln. of a cadmium or zinc salt with an alcoholic soln. of potassium hydroxide and dissolved the precipitate, aided by heat, in an excess of the precipitant; on cooling the soln., hexagonal plates of the hydroxide were produced.

The hydroxides of zinc and cadmium are white. They exist in the colloidal (gelatinous) and crystalline states. Cadmium hydroxide assumes two forms: one prepared by adding sodium hydroxide to soln. of cadmium salts gives rise to the yellow sulphide with sodium sulphide, etc.; and another polymerized one is formed when cadmium soln. are poured into soln. of sodium hydroxide or when they are precipitated hot; this hydroxide produces a red sulphide, with an intermediate dicadmium sulphohydroxide, $\text{Cd}_2\text{S}(\text{OH})_2$, of a fine red colour, but too

unstable for a pigment. J. Morel found the bipyramidal **crystals** of zinc hydroxide belong to the rhombic system, and have the axial ratios : $a : b : c = 0.6048 : 1 : 0.5763$. C. Bodeker obtained regular octahedral crystals by allowing a sat. soln. of zinc hydroxide to stand for a week, and these crystals are thought to be the same as those obtained by A. C. Becquerel, by allowing zinc in contact with copper to stand in a soln. of potassium hydroxide. S. Surawicz explained the existence of rhombic and regular octahedral crystals of zinc hydroxide, and hexagonal zinc oxide by assuming the existence of isomeric, metameric, and polymeric forms of zinc oxide in which the water is regarded as water of crystallization. A. de Schulten said that the crystals of cadmium hydroxide belong to the trigonal system. J. Nicklès gave 2.677 for the **specific gravity** of zinc hydroxide, and E. Filhol gave 3.053; A. de Schulten gave 4.79 for the sp. gr. of cadmium hydroxide at 15°.

H. Rose² found cadmium hydroxide loses its water when heated above 300°. According to R. de Forcrand, colloidal zinc hydroxide obtained by precipitation has not a fixed composition, and at ordinary temp., in the presence of phosphorus pentoxide, it gives off water slowly; and when heated the loss of water is probably accompanied by polymerization, when the temp. rises above 250°. F. Goudriaan found that crystalline zinc hydroxide is metastable at 30° and slowly passes into the oxide. The hydroxide dehydrated at a low temp. takes up water when exposed to a moist atm. When the precipitated hydroxide, washed in an atm. free from carbon dioxide, is dried on a porous plate over sulphuric acid, and then for 3-4 days over phosphorus pentoxide, it has a composition corresponding with $\text{ZnO} : \text{H}_2\text{O} = 3 : 5$, and its heat of soln. in dil. sulphuric acid is 18.48 Cals.; when dried for 3-4 weeks, the ratio is 3 : 4, and the heat of soln. is nearly the same as before. When the 3 : 5 hydroxide is heated for 12 hrs. at 160°, the ratio is 4 : 5 at constant weight, and the heat of soln., 18.83 Cals.; at 250°, the ratio is 5 : 2, and the heat of soln., 23.23 Cals.; and at a red heat, zinc oxide with a heat of soln. 23.91 Cals. is formed. J. Thomsen gave -2.75 Cals. for the heat of hydration of crystallized zinc hydroxide and liquid water; or -4.18 Cals. with solid. G. Massol gave +4.32 Cals.; and R. de Forcrand +2.19 Cals. with water liquid, and 0.76 Cal. with water solid. W. Herz, and A. Hantzsch assumed different modifications are formed during the drying of colloidal zinc hydroxide. J. M. van Bemmelen, and B. Kuriloff have studied the conversion of the colloidal to the crystalline states. The **heats of neutralization** of an eq. of zinc and cadmium hydroxides, $\frac{1}{2}\text{M}(\text{OH})_2$, respectively in hydrochloric acid are 9.89 Cals. and 10.145 Cals. (M. Berthelot); in hydrofluoric acid, 12.55 and 12.78 Cals. (E. Petersen); in hydrocyanic acid, 8.11 and 7.22 Cals. (A. Joannis); in nitric acid, 9.858 and 10.16 Cals. (M. Berthelot); in one eq. of sulphuric acid, 11.702 and 11.91 Cals. (M. Berthelot); and in one eq. of carbonic acid, 5.5 and 6.495 Cals. (M. Berthelot); J. Thomsen found for zinc hydroxide $\text{Zn}(\text{OH})_2 + \text{H}_2\text{SO}_4$ aq., 23.41 Cals.; with 2HCl aq., 19.88 Cals.; with 2HNO_3 aq., 19.83 Cals.; with $2\text{H}_2\text{S}$ aq., 17.97 Cals.; and with $2\text{H}_2\text{C}_2\text{O}_4$, 18.03 Cals. For the **heats of formation** of cadmium and zinc hydroxides, J. Thomsen gave $\text{Zn} + \text{O} + \text{H}_2\text{O} = \text{Zn}(\text{OH})_2 + 82.68$ Cals., and $\text{Cd} + \text{O} + \text{H}_2\text{O} = \text{Cd}(\text{OH})_2 + 65.68$ Cals.

E. Goldstein³ studied the action of cathode rays on the **phosphorescence** of cadmium hydroxide and salts—*vide* cadmium oxide. P. Blackman gave for the **molecular conductivity**, μ , of soln. with a mol of hydroxide in v litres of water :

v .	1000	500	200	100	50	33.3	20
μ .	214	213	210	205	203	98	95

J. K. Wood found that the weaker hydroxyl of zinc hydroxide has a basic dissociation constant of $K = 1.45 \times 10^{-9}$. R. Lorenz found the difference of **potential** of zinc hydroxide with respect to the normal hydrogen electrode, in neutral soln., to be -0.31 volt; and C. Immerwahr, of cadmium hydroxide against 0.05N-NaOH with respect to the calomel electrode 0.750 volt at the beginning and 0.855 volt at the end. S. Meyer found the **magnetic susceptibility** of powdered zinc hydroxide (vacuum=0) is -0.42×10^{-6} mass units at 18°.

The **solubility** of zinc hydroxide in **water** was found by W. Herz⁴ to be 2.6×10^{-6} grm. per litre, and for cadmium hydroxide, he found 2.6×10^{-4} . S. Labendzinsky, and G. Bodländer also made measurements of this constant. Zinc and cadmium hydroxides are amphoteric in that they act both as acids and as bases. According to G. Carrara and G. B. Vespignani, the basic energy of the metallic hydroxides corresponds with their position in the periodic table, for they fall in the order of decreasing strength: Mg, Cu, Zn, Cd, Al, Fe. H. W. F. Wackenroder found that when zinc oxide is boiled with an aq. soln. of **sodium or potassium carbonate**, some alkali is adsorbed, and the oxide exhibits an alkaline reaction; the alkali can be removed by a prolonged washing with water. According to A. Colson, when a soln. of **sodium sulphate** is added to zinc oxide (neutral to phenolphthalein) suspended in water, the mixture becomes increasingly alkaline, owing to the liberation of sodium hydroxide, and the formation of what he regarded as a basic sulphate, $(\text{Zn.O.ZnOH})_2\text{SO}_4$. W. Bersch found that freshly precipitated cadmium hydroxide dissolves in aq. soln. of **potassium and sodium halides or thiocyanates** liberating the alkali hydroxide; the calculated heats of reaction are all negative and with KCl is -818 cal.; with NaCl, -754 cal.; KBr, -738 cal.; NaBr, -744 cal.; KI, -716 cal.; and NaI, -716 cal. W. Biltz and F. Zimmermann found that when well-washed zinc or cadmium hydroxide is treated with $\frac{1}{10}N$ -**silver nitrate**, the hydroxide is discoloured owing to the formation of silver oxide; and $\frac{1}{10}N$ -**mercuric nitrate** produces a yellowish-red discoloration for an analogous reason. H. N. Stokes found that **ferrous sulphide** does not react with zinc hydroxide in the cold or at 100° , but at 160° ferrous hydroxide and zinc sulphide are slowly formed. According to G. Lunge and H. Landolt, if **chlorine** be passed into water in which zinc hydroxide is suspended, zinc hypochlorite and chlorate are formed in quantities which increase as the temp. rises. R. von Wagner found zinc hydroxide is slowly converted into zinc sulphide by the action of **hydrogen sulphide**. R. Fink investigated the behaviour of zinc hydroxide towards soln. of metallic salts.

F. J. Malaguti,⁵ and A. Müller observed that rhombic crystals containing zinc oxide and ammonia are formed on the painted brick-work of a privy. T. Weyl noted that zinc oxide absorbs ammonia gas at a low temp., forming **zinc diammino-oxide**, $\text{ZnO}(\text{NH}_3)_2$. Zinc hydroxide was found by E. Firnhaber to be readily dissolved by aq. **ammonia**, while the ignited oxide does not dissolve at all; but, according to R. Schindler, the ignited oxide is sparingly soluble in that menstruum, and its solubility is augmented by the presence of traces of ammonium and potassium salts—the phosphates were found to be most favourable, then follow arsenates, chlorides, sulphates, nitrates, acetates, carbonates, tartrates, citrates, and sulphites; succinates and benzoates are favourable only in dil. soln.; borates, iodides, chlorates, arsenites, oxalates, and gallates unite with the zinc oxide. F. F. Runge found that zinc in contact with iron dissolves slowly in aq. ammonia with the evolution of hydrogen and the formation of a colourless soln. The zinc dissolves in the absence of iron, but more slowly. A soln. can be obtained containing 3.95 parts of zinc oxide, and 7.68 parts of ammonia per 100 parts of soln. The conc. soln. becomes turbid when diluted with over 15 times its vol. of water. According to G. C. Wittstein, and A. Bonnet, when the soln. is evaporated in air, it furnishes needle-like crystals containing carbonates of zinc and ammonium, and when evaporated on a sand-bath, it gives an odourless mass, which is soluble in water, and which gives off ammonia when treated with potassium hydroxide. J. J. Berzelius found that lime-water, strontia-water, or baryta-water precipitates from the ammoniacal soln. a compound (or mixture) of zinc oxide with the earthy base. A. M. Comey and C. L. Jackson could not prepare ammonium zincate.

D. P. Konowaloff found that the vap. press., p , of ammonia in aq. soln. is depressed in the presence of dissolved salt such that if p_1 represents the press. of the dissolved salt and n and m the number of mols of ammonia and salt respectively in a litre of soln., then $p_1 = p(n - km)$, where k is a constant whose value is 4 for

cadmium and zinc nitrates. This is taken to mean that each atom of zinc or cadmium is probably united with 4 mols of ammonia—say, **zinc tetrammino-oxide**, $\text{Zn}(\text{NH}_3)_4\text{O}$. From solubility determinations and measurements of the e.m.f. of conc. cells, H. Euler also deduced that the complex cation in ammoniacal soln. of zinc salts is $\text{Zn}(\text{NH}_4)_2$, and W. Bonsdorff measured the electrical conductivity of soln. of zinc or cadmium hydroxide in aqua ammonia. According to W. Bonsdorff, the solubility of zinc hydroxide in aq. ammonia at 25° is

Normality of NH_3 .	0.321	0.643	1.215	1.928	2.570	3.213
ZnO, grms. per litre	0.34	0.845	2.70	5.07	7.01	10.16

H. Euler, and W. Bonsdorff also inferred from measurements of the transport numbers that a measurable amount of *ammonium zincate* is not present in ammoniacal soln. of zinc oxide. W. Herz found that zinc is present in the diffuse from ammoniacal soln. of zinc hydroxide. B. B. Kuriloff found that the excess of ammonia necessary to dissolve the precipitate formed when ammonia is added to a soln. of zinc chloride or sulphate is greater the more dil. the soln. W. Herz studied the equilibrium represented by the scheme $\text{Zn}(\text{OH})_2 + 2\text{NH}_4\text{Cl} \rightleftharpoons \text{ZnCl}_2 + 2\text{NH}_4\text{OH}$; similarly also with soln. of zinc sulphate and nitrate, and with cadmium salts. W. Herz found that the solubility of zinc oxide is less with the mono-substituted ammonias, and this the more the higher the mol. wt. of the amine; zinc oxide is not soluble in the disubstituted ammonias. A. Bonnet found plant fibres absorb zinc oxide from an ammoniacal soln. when treated with an alkali, and it is not removed by washing. A. Windaus studied the action of an ammoniacal soln. of zinc oxide on sugars; and K. Inouje, on *d*-galactose and *d*-arabinose.

F. Stromeyer found that when cadmium oxide is treated with aq. ammonia, its colour first becomes white, and it then dissolves; the soln. on evaporation forms the gelatinous hydroxide; while H. W. F. Wackenroder noted that potassium hydroxide precipitates cadmium hydroxide from the ammoniacal soln. of the oxide. The solubility of cadmium hydroxide in aq. ammonia has been measured by H. Euler, and W. Bonsdorff; the latter found at 25° :

Normality of NH_3 .	0.5	1.0	1.8	4.6
CdO	0.24	0.62	1.33	4.92 grms. per litre

From the solubility of the oxide in aq. ammonia, and the conductivity and potential of the soln., W. Bonsdorff showed that the ammoniacal soln. probably contains complexes of cadmium tetrammino-oxide, $\text{Cd}(\text{NH}_3)_4\text{O}$; and H. Euler found the equilibrium constant to be $k=1.0 \times 10^{-7}$. The complexes were studied by W. Gaus, H. M. Dawson and J. McCrae, W. Bonsdorff, etc. E. Ebler compared the tendency of the different metals to form complexes with ammonia. W. Bonsdorff found that the ammonia-base formed by cadmium oxide is rather weaker than the one formed with nickel oxide, and he found that the stability of the complex with zinc is about 100 times greater than that of the complex with cadmium.

The peptization of zinc hydroxide by a soln. of sodium hydroxide in glycerol or sugar is a case of chemical action because the electrical conductivity of the alkali soln. is lowered by the addition of the zinc hydroxide—*vide* mercuric hydroxide. As previously indicated, zinc dissolves slowly in a soln. of **potassium or sodium hydroxide**, forming what is regarded as a soln. of alkali zincate. The ignited oxide dissolves slowly, and the hydrated oxide rapidly in the alkali lye. According to G. Bonnet,⁶ two parts of zinc oxide dissolve in five parts of potash lye of sp. gr. 1.3; and W. J. Sharwood noted that the solubility of zinc oxide is less with soln. of potassium hydroxide than with soln. of sodium hydroxide, and that with dil., say $\frac{1}{10}N$, soln. of the alkali-lye—thus cold soln. with 100 mols of potassium hydroxide or sodium hydroxide dissolved respectively 2.4 and 4.5 mols of zinc oxide; hot soln. dissolve rather more, but when boiled, the soln. is decomposed and zinc oxide is precipitated. Dil. soln. of alkali-lye are readily decomposed; and conc. soln.

become turbid when diluted with a large proportion of water. A. B. Prescott found that more than four mols of KOH are needed for the soln. of one mol of $\text{Zn}(\text{OH})_2$, and zinc hydroxide is precipitated when the sat. soln. is diluted with 12 vols. of water. About three times as much alkali is needed for the soln. of the zinc hydroxide at 50° as at 16° – 17° . According to W. Herz, freshly precipitated zinc hydroxide readily dissolves in excess of potassium hydroxide and is completely dissolved when for 1 Zn there are 6 OH groups. If, however, the zinc hydroxide is previously dried at 60° – 70° in a vacuum desiccator, it becomes comparatively difficult to dissolve, and is only completely dissolved when for 1 Zn there are 35.8 OH groups in the soln. B. Kuriloff found that when potassium hydroxide is added to a soln. of zinc chloride or sulphate, the excess needed to dissolve the precipitate first formed is greater the more dil. the soln., and greater for the sulphate than for the chloride. J. K. Wood found that the solubility of zinc hydroxide in soln. of sodium hydroxide at 25° is:

Mols NaOH	:	:	0.2636	0.3871	0.5414	0.9280
Mols $\text{Zn}(\text{OH})_2$:	:	0.00311	0.0057	0.0129	0.0425

J. Rubenbauer found that the quantity of zinc hydroxide dissolved by soln. of sodium hydroxide varies with the conc. of the latter. There is a maximum solubility for the atomic ratio: $\text{Zn} : \text{Na} = 1 : 3$. The maximum is attributed to the decreased solubility owing to increasing hydrolysis the more dil. the soln., and to the dehydration of the hydroxide by the conc. alkali soln. whereby it is transformed into a less soluble form. When zinc hydroxide is treated with alkali, more dissolves at first than corresponds with the true equilibrium under the prevailing conditions, for such soln. spontaneously deposit more or less zinc hydroxide according to the conc. When potassium hydroxide is gradually added to a soln. of zinc sulphate, zinc hydroxide is precipitated, and subsequently redissolved. Fig. 25 shows the relation

FIG. 25.—The Precipitation of Zinc Hydroxide by Potassium Hydroxide.

between the amount of zinc hydroxide precipitated and the proportion of potassium hydroxide in soln. The precipitation of zinc hydroxide is complete when 1.62 mols of potassium hydroxide per mol of zinc sulphate are present in the soln., and soln. is complete only when 13.2 mols of potassium hydroxide per mol of zinc sulphate are present.

According to A. Hantzsch, zinc hydroxide separates from its alkaline soln. as a fine, dense powder soluble with difficulty in sodium hydroxide soln., but he does not believe an isomeric or polymeric modification is formed, rather is the diminished solubility to be attributed to (i) a physical alteration of the surface, and (ii) to a dehydration of the hydroxide by the alkali. A. W. Buchner, and R. Schindler noted that when the soln. of zinc hydroxide in potassium hydroxide is exposed to air, a precipitate containing zinc oxide, potassium hydroxide, and carbon dioxide is formed; if the soln. be boiled, zinc hydroxide alone is precipitated. If some silica is present, a double silicate of zinc and potassium is precipitated.

R. Kremann found that when an alkaline soln. of zinc hydroxide is electrolyzed, the proportion of zinc at the anode increases, and the anion is in consequence assumed to contain zinc, and the soln. is not to be regarded as a colloidal soln. of zinc hydroxide. G. Bredig, however, objected that the migration experiments do not prove that anionic complexes are present because colloidal suspensions themselves migrate under the influence of an electric current; but R. Kremann replied that the order of magnitude of the migration of zinc in alkaline soln. shows that the phenomenon is not due to migration in colloidal soln. W. Biltz found that during electrolysis colloidal zinc and cadmium hydroxides migrate to the cathode.

W. Herz found that when a soln. of zinc hydroxide in alkali lye is dialyzed, very little passes through the membrane, but hydroxide is precipitated on the membrane, and he therefore inferred that the alkali soln. contains part of the zinc as zincate, and part as colloidal oxide. F. G. Cottrell also studied the rate of diffusion of these soln. When an alkaline soln. of zinc hydroxide is warmed or when sodium chloride is added, most of the zinc hydroxide separates out, and from the electrical conductivity, and the effect on the speed of hydrolysis of ethyl acetate, A. Hantzsch inferred that the zinc hydroxide is an extremely weak acid, and is mainly present in soln. in the colloidal form; that the hydroxide acts as a monobasic acid; and that there are no grounds for assuming the existence of a dibasic acid, H_2ZnO_2 . A. Hantzsch said:

Zinc and beryllium hydroxides behave like very weak acids, but the former scarcely deserves the name acid because the existence of alkali zincates in aq. soln. can no longer be established for zinc hydroxide spontaneously separated from the soln. (almost the whole of it under certain conditions) when flocculated by warming or by treatment with sodium chloride, as in the case of colloidal soln. The main quantity of zinc hydroxide in these soln. is therefore present in the colloidal form.

O. Klein suggested that A. Hantzsch was misled by using very dil. soln., for the solubility of the oxide is proportional to the amount of alkali present, and this agrees with the assumption that a definite compound is formed. As previously indicated, O. Klein assumed that there are three modifications of the hydroxide—*vide* beryllium hydroxide. By dropping a soln. of zinc sulphate into a soln. of potassium hydroxide until the precipitate just fails to dissolve, it is assumed that the soln. is just sat. with the most soluble and least stable *A*-form; if the soln. be allowed to stand it deposits crystals of the *B*-form; and these soon pass into the least soluble *C*-form. Expressing conc. in mols per litre, at 18° ,

	<i>A</i> -form			<i>B</i> -form			<i>C</i> -form		
Conc. KOH.	0.540	0.330	0.100	0.310	0.200	0.06	0.280	0.190	0.0031
Conc. $\text{Zn}(\text{OH})_2$	2.78	2.02	0.90	2.76	2.00	0.94	6.25	0.323	0.26

The whole of the results are represented by the graphs, Fig. 26. It is assumed that the *A*-form is $\text{H}_2\text{Zn}_2\text{O}_3$, which ionizes $\text{H}_2\text{Zn}_2\text{O}_3 = 2\text{H}^+ + \text{Zn}_2\text{O}_3''$, so that $[\text{H}]^2[\text{Zn}_2\text{O}_3''] = k_1 = 0.68 \times 10^{-29}$. The *B*-form is assumed to be H_2ZnO_2 , which ionizes $\text{H}_2\text{ZnO}_2 = 2\text{H}^+ + \text{ZnO}_2''$, so that $[\text{H}]^2[\text{ZnO}_2''] = k_2 = 0.71 \times 10^{-29}$. The *C*-form is similar in composition to the *B*-form, and its constant $k_3 = 0.27 \times 10^{-29}$. These assumptions agree with the observations of W. Herz, J. K. Wood, and J. Rubenbauer. O. Klein added that there is no evidence of colloidal zinc hydroxide in the soln.

G. Carrara and G. B. Vespignani measured the electrical conductivity of soln. of 0.03575 grm. of zinc oxide in 100 c.c. of $\frac{N}{5}$ -KOH, when the soln. is so diluted that it contains an eq. of KOH in v litres, and found:

v	5	10	20	40	80	160	320	640
λ	200.23	202.10	212.98	215.48	215.44	213.92	207.36	190.72

From electrometric measurements F. Kunschert inferred that a soln. of zinc hydroxide in conc. sodium hydroxide contains sodium zincate, Na_2ZnO_2 , *i.e.* the sodium salt of dibasic zincic acid, H_2ZnO_2 , which furnishes bivalent anions ZnO_2'' ;

FIG. 26.—Solubility of the Different Forms of Zinc Hydroxide in Solutions of Potassium Hydroxide, at 18° .

with dil soln. of the alkali hydroxide sodium hydrozincate, NaHZnO_2 , is present, and it furnishes univalent ions HZnO_2' . Both salts are stable only in the presence of an excess of alkali. G. Bodländer calculated the stability constant and the energy of formation of HZnO_2 , and obtained respectively 1.9×10^6 and $8340 + 670 \log [\text{Zn}][\text{OH}]^3/C$ cals., where C denotes the conc. of the complex ion in mols per litre; F. Kunschert obtained respectively 2.5×10^6 and 16,520 cal. at 18° . G. Bodländer also found the e.m.f. of the soln. of sodium zincate in contact with the metal against the hydrogen electrode, to be $1.130 - 0.029 \log C/[\text{OH}]^3$; and for the heat of formation in cal. per gram-ion of the complex from the metal and anions, he obtained $52600 - 1340 \log C/[\text{OH}]^3$. J. K. Wood found 60 per cent. hydrolysis in a $\frac{1}{10}N$ -soln. of sodium zincate.

J. Moir regards the dissolution of zinc hydroxide by a soln. of an alkali hydroxide as an equilibrium phenomenon between the alkali and zincic acid. The equilibrium may be reached from both sides: (i) adding an excess of zinc hydroxide to an alkali lye; or (ii) diluting a conc. soln. sat. with zinc hydroxide. J. Moir found no evidence of the existence of a definite compound in his solubility curves of zinc hydroxide in soln. of $0.01N$ - to $7N$ -alkali. If x represents the number of mols of potassium or sodium hydroxide, and y the number of mols of zinc oxide dissolved, J. Moir found the observed results could be approximately represented by the empirical relation: $y(x+2) = 0.004x(79x+6)$. The observed results obtained by diluting a sat. soln. are sometimes abnormal owing to the persistence of a state of supersaturation, but in time, a state of stable equilibrium is attained. P. Schoop has studied the electrochemical formation of alkali zincate soln.

A. Bonnet found that when a soln. of potassium zincate is evaporated to dryness, and the residue fused, an enamel-like mass is formed from which water extracts the alkali, and when the soln. is treated with eight vols. of alcohol, nearly all the zinc oxide is deposited. F. Wöhler obtained a basic zinc carbonate by exposing in air a soln. of zinc oxide in one of sodium hydroxide. M. Laux found that when a conc. soln. of potassium zincate is covered with a layer of alcohol, small shining crystals of **potassium zincate**, K_2ZnO_2 , containing $\text{ZnO} : \text{K}_2\text{O} = 1 : 1$, are deposited; the crystals are readily decomposed by water, and when the soln. is boiled, a white powder is formed containing $\text{ZnO} : \text{K}_2\text{O} = 2 : 1$. A. L. Voegelé obtained this compound in a secondary reaction between electrolytically formed potassium hydroxide and a zinc cathode; G. Carrara and G. B. Vespignani obtained it by the dissolution of zinc oxide in an excess of a moderately conc. soln. of potassium hydroxide; and W. J. Sharwood by the soln. of zinc cyanide in a dil. soln. containing two or more than two mols of potassium hydroxide. E. Frémy reported that when alcohol is added to a conc. soln. of potassium zincate, long needles of *potassium dizincate*, $\text{K}_2\text{Zn}_2\text{O}_3$, with $\text{ZnO} : \text{K}_2\text{O} = 2 : 1$, are deposited; these are immediately decomposed by water, forming zinc and potassium hydroxides. A. M. Comey and C. L. Jackson did not confirm the existence of this compound, but obtained instead amorphous zinc oxide. W. J. Sharwood claimed to have made a compound, $\text{K}_2\text{ZnO}_2 \cdot 8\text{KOH}$, by the action of potassium cyanide on zinc oxide. J. Moir found no grounds for assuming the existence of these products as chemical individuals.

A. M. Comey and C. L. Jackson found that when alcohol is shaken with a conc. soln. of zinc oxide in sodium hydroxide, the liquid separates into two layers. The lower aq. layer was treated with alcohol two or three times when it solidified to a crystalline mass which melts at about 70° , and has the composition $\text{Na}_4\text{H}_2\text{Zn}_3\text{O}_6 \cdot 17\text{H}_2\text{O}$. The alcoholic soln. deposits lustrous needles which do not melt at 300° , and have the composition $2(\text{NaO} \cdot \text{ZnOH}) \cdot 7\text{H}_2\text{O}$, and correspond with E. Frémy's potassium compound. F. Förster and O. Günther could prepare only one **sodium zincate**, $\text{NaO} \cdot \text{Zn} \cdot \text{OH} \cdot 3\text{H}_2\text{O}$, in white needles with a silky lustre by crystallization from a soln. of zinc in sodium hydroxide. E. Jordis obtained crystals of sodium zincate, $\text{Zn}(\text{ONa})_2 \cdot n\text{H}_2\text{O}$, in a galvanic cell in which zinc was employed as a negative pole in a soln. of sodium hydroxide. F. Goudriaan found only one stable sodium zincate, $\text{Na}_2\text{ZnO}_2 \cdot 4\text{H}_2\text{O}$, at 30° , and the conditions of

equilibrium are indicated in Table III, and Fig. 27. Sodium zincate forms what is called an *incongruent solution*, for, on adding water, it does not yield a

TABLE III.—SYSTEM $\text{Na}_2\text{O}-\text{ZnO}-\text{H}_2\text{O}$ AT 30° .

40.9	1.1	58.0	Na ₂ O.3H ₂ O
41.9	0.0	58.1	Na ₂ O.3H ₂ O

simple soln., but one of the components separates out. Not only does the addition of water to the solid salt cause a separation of zinc oxide, but the dilution of the soln. of sodium hydroxide produces the same result. The range of stability is indicated in Table III and in the accompanying diagram. The salt is decomposed by soln. below a conc. of one part of sodium hydroxide to two parts of water. The crystals are also hydrolyzed by 96 per cent. alcohol, and a mixture of amorphous zinc oxide or hydroxide and sodium zincate is formed, the relative proportions of the two depend on the proportion of alcohol employed and the duration of the operation. These facts also explain the various results obtained by different investigators, and show that many mixtures must have been

FIG. 27.—Ternary System: $\text{ZnO}-\text{Na}_2\text{O}$
— H_2O at 30° .

that many mixtures must have been reported as chemical individuals. F. Goudriaan studied the conditions of equilibrium of the ternary system: $\text{Na}_2\text{O}-\text{ZnO}-\text{H}_2\text{O}$ at 30° ; and a few data from his list are indicated in Table III. The results are plotted in Fig. 27, where the curve AB represents the increasing solubility of zinc oxide in soln. of increasing conc. in sodium hydroxide; BC , the solubility with $\text{Na}_2\text{O} \cdot \text{ZnO} \cdot 4\text{H}_2\text{O}$ as solid phase; and CD , the solubility with $\text{Na}_2\text{O} \cdot 3\text{H}_2\text{O}$, *i.e.* $\text{NaOH} \cdot \text{H}_2\text{O}$, as solid phase. AF represents the metastable solubility-curve of crystalline zinc hydroxide, so that other circumstances being equal, the solubility of crystalline zinc hydroxide is greater than that of zinc oxide. Consequently, at 30° there is only one stable sodium zincate, namely, $\text{Na}_2\text{ZnO}_2 \cdot 4\text{H}_2\text{O}$. All the other zincates which have been reported must be regarded as metastable or as non-existent.

According to C. U. Shepard, the mineral *calciozincite* from Franklin, New Jersey, has the composition CaO, 7.56; ZnO, 81.00; H₂O, 4.26 per cent.; its sp. gr. is 3.95. M. Reiche obtained a cement which was very hard, and resistant towards salt soln., by heating a mixture of a mol of zinc oxide with two mols of calcium oxide in the presence of water, and under a high press. G. Bertrand prepared

calcium zincate, $\text{CaH}_2(\text{ZnO}_2)_{2.4}\text{H}_2\text{O}$, or $\text{Ca}(\text{O.ZnOH})_{2.4}\text{H}_2\text{O}$, in brilliant lozenge-shaped plates when ammonia is withdrawn from the sat. ammoniacal soln. of zinc oxide and lime water, by evaporation over sulphuric acid. The salt absorbs carbon dioxide from air when it becomes opaque, and is decomposed by water into zinc oxide and lime; it does not lose water at 125° , but is decomposed at a dull red heat. The corresponding **strontium zincate**, $\text{SrH}_2(\text{ZnO}_2)_{2.7}\text{H}_2\text{O}$, was made in a similar manner in the form of flattened lozenge-shaped crystals; and **barium zincate**, $\text{BaH}_2(\text{ZnO}_2)_{2.7}\text{H}_2\text{O}$, crystallized in brilliant flattened needles.

According to S. Meunier,⁷ cadmium oxide dissolves in molten potassium hydroxide, and, after washing the potassium hydroxide away from the cold mass, yellow crystals of **potassium cadmate** remain; they contain cadmium oxide, potassium hydroxide, and water. They are insoluble in water, but are slowly decomposed when in contact with that menstruum. Similar results were obtained with sodium hydroxide—**sodium cadmate**. L. Rolla and R. Salani found that fused sodium hydroxide shows two points of cathodic decomposition, the lower one, 1.20 volts, corresponding with the discharge potential of the hydrogen-ions, the higher point, corresponding with the discharge potential of the sodium-ions, has the value 2.08 volts at 460° , 2.13 volts at 412° , and 2.24 at 364° . With the mixtures containing zinc or cadmium oxide, the decomposition occurring is that of zinc or cadmium hydroxide, the decomposition tensions for the zinc- and cadmium-ions being, respectively, 1.80 and 0.89 volts. When zinc oxide is fused with **magnesium chloride**, K. A. Hofmann and K. Höschele found volatile zinc chloride is formed.

Zinc and cadmium peroxides.—L. J. Thénard⁸ obtained *deutoxide de zinc* or zinc peroxide by treating zinc hydroxide with hydrogen peroxide at 0° . The gelatinous mass gives off oxygen slowly at ordinary temp., and rapidly at 100° . When treated with acids, it forms a zinc salt and hydrogen peroxide. L. J. Thénard found that the additional oxygen taken up was rather more than half that originally present in the monoxide, and concluded that per-oxidation was incomplete. R. Haas confirmed these results, and he found the composition of the product varied between Zn_5O_8 and Zn_3O_5 , and he considered the presence of hydroxide is necessary for the formation of the peroxide. His product was a white, odourless, tasteless, neutral, gelatinous mass; fairly stable to acids, water, and heat. When a soln. of zinc sulphate is added to an excess of a soln. of sodium hydroxide containing hydrogen peroxide, zinc is precipitated in a peroxidized form. R. de Forcranc obtained a number of intermediate peroxides. For example, $4\text{ZnO.H}_2\text{O.3H}_2\text{O}_2$, or, less probably, $\text{Zn}_4\text{O}_7.4\text{H}_2\text{O}$, is obtained by shaking zinc hydroxide suspended in water with hydrogen peroxide containing 2 to 3 times as much active oxygen as is needed to convert the zinc oxide into the dioxide, ZnO_2 . The product loses no oxygen in a desiccator at ordinary temp. When heated to 100° , it produces **zinc hydroperoxide**, $3\text{ZnO.H}_2\text{O.2H}_2\text{O}_2$, or, less probably, $\text{Zn}_3\text{O}_5.3\text{H}_2\text{O}$. At 190° , it decomposes explosively into hydrated zinc oxide. When $4\text{ZnO.H}_2\text{O.3H}_2\text{O}_2$ is treated with an excess of hydrogen peroxide, it forms $\text{ZnO.H}_2\text{O.H}_2\text{O}_2$, less probably formulated $\text{ZnO}_2.2\text{H}_2\text{O}$. This compound produces $3\text{ZnO.2H}_2\text{O}_2$, which is less probably represented by $\text{Zn}_3\text{O}_5.2\text{H}_2\text{O}$. B. B. Kuriloff claimed that only one definite peroxide, $\text{ZnO}_2.\text{Zn}(\text{OH})_2$, has been proved to exist, and he regards this as the end-product of the oxidation. J. F. Eijkman boiled a soln. of zinc sulphate, which had been treated with enough aq. ammonia to dissolve the precipitate first formed, with 30 per cent. hydrogen peroxide. The pale-yellow granular precipitate is stable up to nearly 130° . It is soluble in aq. sodium hydroxide with the evolution of oxygen; it explodes when heated to about 212° ; and when mixed with aluminium or zinc powder, it burns with a dazzling light. F. W. Sjöström left ignited zinc oxide for several hours in contact with the calculated amount of a 30 per cent. soln. of hydrogen peroxide at -10° . The product was a pasty mass above 2° , and when dried at 35° – 40° on a porous plate over soda-lime, it furnished a white powder corresponding with $\text{HO.Zn}_2\text{O.O.OH}$.

It is not clear whether the product of the action of hydrogen peroxide on zinc oxide is to be regarded as a salt of hydrogen peroxide, or as an addition product with hydrogen peroxide of crystallization. The above-mentioned products can be regarded as mixtures of zinc peroxide with the unconverted hydroxide. O. Carrasco digested zinc oxide with an ethereal soln. of hydrogen peroxide in excess and obtained a product which, when dried at 60°–70°, had the composition $\text{Zn}_4\text{O}_7 \cdot 2\text{H}_2\text{O}$. It is stable at 70°–80°, and is not affected by cold water, but with hot water at 100°, it forms $\text{Zn}_3\text{O}_5 \cdot \text{H}_2\text{O}$. Both compounds are reddish-yellow powders which explode near 212°. O. Carrasco claimed that these two products are hydrated peroxides, and not additive compounds of condensed hydrates of zinc oxide with hydrogen peroxide, because they contain less water mols. than active oxygen atoms. In structure they differ from the peroxides of other metals, and are to be considered as *perzincic acids* of the following probable constitutions: $\text{HO} \cdot \text{Zn} \cdot \text{O} \cdot \text{O} \cdot \text{Zn} \cdot \text{O} \cdot \text{O} \cdot \text{Zn} \cdot \text{O} \cdot \text{O} \cdot \text{H}$ and $\text{HO} \cdot \text{Zn} \cdot \text{O} \cdot \text{O} \cdot \text{Zn} \cdot \text{O} \cdot \text{O} \cdot \text{Zn} \cdot \text{OH}$. According to P. Kazanecky, the action of a 30 per cent. soln. of hydrogen peroxide soln. on potassium, sodium, or ammonium zincoxide results in the formation of a white, microcrystalline precipitate, which is found to consist of a zinc peroxide, $\text{ZnO}_2 \cdot \text{H}_2\text{O}$, containing an admixture of zinc carbonate, the presence of the latter being due to the strong alkalinity of the soln. in which the reaction takes place. When the peroxide is heated, explosive evolution of oxygen and water occurs at 178°. When heated with dil. sulphuric acid, it yields hydrogen peroxide, whilst, with conc. hydrochloric acid, chlorine is evolved. The peroxide must, indeed, be regarded as consisting of three molecules of ZnO_2 , one of which is the dioxide corresponding with an acid anhydride, the other two representing true zinc peroxide:

P. Kazanecky, and F. W. Sjöström are agreed that those zinc peroxides which have been described previously by various authors consist of mixtures derived either from zinc hydroxide, $\text{Zn}(\text{OH})_2$, or from zinc hydroperoxide, $\text{HO} \cdot \text{Zn} \cdot \text{O} \cdot \text{Zn} \cdot \text{OH}$, and the representatives are respectively $\text{HO} \cdot \text{Zn} \cdot \text{O} \cdot \text{OH}$, or $\text{HO} \cdot \text{Zn} \cdot \text{O} \cdot \text{Zn} \cdot \text{O} \cdot \text{OH}$. E. Ebler and R. L. Krause proposed the term *peroxydate* for additive compounds of hydrogen peroxide, and *peroxite* for the salts of hydrogen peroxide regarded as a dibasic acid. A soln. of hydrogen peroxide is extracted with ether, and the extract is dried with anhydrous sodium sulphate and added gradually to a cooled soln. of zinc ethyl in dry ether. Ethane is evolved, and a white, amorphous precipitate is formed, which is washed with ether and dried in a vacuum. It has the composition $\text{ZnO}_2 \cdot \frac{1}{2}\text{H}_2\text{O}$, is slowly decomposed by acids, yielding hydrogen peroxide, or violently by heat, evolving oxygen. Water hydrolyzes it very slowly, an equilibrium being reached. The compound acts on a photographic plate.

Zinc peroxides have been recommended in various forms as antiseptics because they are odourless, and non-irritant. There are various preparations. E. Merck's *zinc perhydrol* is made by treating dry zinc oxide with pure hydrogen peroxide; F. J. Homeyer's preparation was made by treating sodium or barium peroxide with zinc chloride; M. Frenkel's *ectogan* contains 20 to 60 per cent. of zinc peroxide; R. Wolfenstein precipitated zinc peroxide on alumina; and F. Hinz's preparation was made by the electrolysis of zinc chloride with hydrogen peroxide about the cathode. R. von Foregger and H. Philipp found commercial zinc peroxide averaged 50 per cent. ZnO_2 , along with zinc hydroxide and moisture. It is a yellowish-white powder of sp. gr. 1.571; it is very stable, and does not lose its available oxygen at 170°. At 100°, the moisture evaporates without affecting the product itself, so that by this procedure the substance gains in percentage of peroxide. Zinc peroxide suspended in water is very permanent and very slightly soluble (one part in 45,500). In acids of any kind it is readily soluble. Organic matter, if moist, or if acid in reaction, decomposes it gradually. It is indifferent to mineral hydrocarbons, inasmuch as they contain no free acid. This characteristic is essential for the preparation of ointments, a form in which it is widely used.

R. Haas made cadmium peroxide, analogous to zinc peroxide, with a composition ranging from Cd_5O_8 to Cd_3O_5 . G. Krüss believed that pure cadmium peroxide could be made by the action of hydrogen peroxide on cadmium hydroxide. B. B. Kuriloff made what approximated to $\text{CdO}_2 \cdot \text{Cd}(\text{OH})_2$, by repeatedly evaporating to dryness a mixture of cadmium hydroxide and a dil. soln. of hydrogen peroxide. The yellow crystalline powder is insoluble in aq. ammonia; it yields hydrogen peroxide when treated with acids; and it is decomposed at 180° . J. F. Eijkman obtained what he regarded as $4\text{CdO}_2 \cdot \text{Cd}(\text{OH})_2$, by boiling an ammoniacal soln. of cadmium hydroxide with hydrogen peroxide. The yellow powder is darkened by exposure to light, and superficially forms cadmium oxide; it explodes at 190° ; and is not dissolved by a soln. of sodium hydroxide. W. Manchot reported that cadmium oxide formed by the low temp. oxidation of the metal in air, contains some dioxide, CdO_2 .

§ 11. Zinc and Cadmium Fluorides

H. Moissan found ¹ that fluorine has very little action on zinc in the cold, but when heated, the zinc burns with a brilliant light, forming **zinc fluoride**, ZnF_2 . J. L. Gay Lussac and L. J. Thénard obtained a gelatinous precipitate by adding potassium fluoride to a soln. of zinc sulphate, and the precipitate when dried formed white powder; a similar product was obtained by the action of hydrofluoric acid on zinc. J. J. Berzelius likewise made **cadmium fluoride**, CdF_2 , by the evaporation of a soln. of cadmium in hydrofluoric acid. W. Mills prepared fluoride of the metals whose salts are precipitable by ammonia—e.g. aluminium, chromium, magnesium, manganese, zinc, etc.—by adding ammonium fluoride, or ammonia and hydrofluoric acid, to a soln. of the chloride or sulphate of the metal. On evaporating soln. of zinc fluoride in dil. hydrofluoric acid, small white rhombic crystals of **tetrahydrated zinc fluoride**, $\text{ZnF}_2 \cdot 4\text{H}_2\text{O}$, are obtained. J. C. G. de Marignac made anhydrous **zinc fluoride**, ZnF_2 , by heating the hydrated salt to 100° ; H. Moissan, by washing the product of the action of hydrofluoric acid on zinc carbonate and drying at 200° ; C. Poulenc, by the action of hydrogen fluoride on zinc or zinc oxide at a red heat, or on hydrated zinc chloride at 800° – 900° ; G. Gallo ² made anhydrous zinc fluoride by heating the hydrated fluoride, or zinc fluosilicate for 2 hrs. at 125° ; C. Poulenc made crystals of anhydrous cadmium fluoride, CdF_2 , by the same process as he employed for the zinc salt.

Anhydrous zinc fluoride forms colourless needle-like crystals belonging either to the monoclinic or triclinic system. The crystals of tetrahydrated zinc fluoride belong to the rhombic system with axial ratios, according to J. C. G. de Marignac, $a:b:c=0.6054:1:0.4396$. The sp. gr. of anhydrous zinc fluoride is 4.84 (15°), according to C. Poulenc, and, according to F. W. Clarke, 4.612 (12°) and 4.556 (17°);

for anhydrous cadmium fluoride, C. Poulenc gives 6.64 (15°), and F. W. Clarke, 5.994 (22°). W. Biltz said that, assuming the sp. gr. of zinc and cadmium fluorides are 4.84 and 5.994 , the respective mol. vol. are 21.4 and 26.09 . G. Gallo gave 734° for the m.p. of zinc fluoride. The m.p. of cadmium fluoride, according to T. Carnelley, is 520° , but, according to O. Ruff and W. Plato, it is over 1000° ; the best representative values for the m.p. of zinc and cadmium fluorides are respectively 734° and 520° . Zinc fluoride is perceptibly volatile at 800° , but cadmium fluoride not even at 1200° . According to E. Petersen, the heat of neutralization $\text{Zn}(\text{OH})_2 + 2\text{HF}_{\text{aq.}} = 25.10$ Cals., and $\text{Cd}(\text{OH})_2 + 2\text{HF}_{\text{aq.}} = 15.56$ Cals.; O. Mulert gave for $(\text{CdO}, 2\text{HF}) = 23.48$ cals. per mol; and, according to M. Berthelot, $(\text{Zn}, \text{F}_2, \text{aq.})$, 140 Cals.; and $(\text{Cd}, \text{F}_2, \text{aq.})$, 25.56 Cals. at 15° .

According to J. J. Berzelius, tetrahydrated zinc fluoride dissolves sparingly in water, but more readily in water acidified with hydrofluoric, hydrochloric, or nitric acid; a similar observation was made with cadmium fluoride, and A. Jäger explained the phenomenon by assuming that an acid or complex compound is formed. C. W. Scheele, and J. L. Gay Lussac and L. J. Thénard obtained **zinc hydrofluoride**, or **zinc acid fluoride**, by dissolving the normal fluoride in hydrofluoric acid, or zinc in an excess of the same acid. The solubility of cadmium fluoride in water at 25° is 0.289 mol. per litre—or 100 c.c. of a sat. aq. sol. of cadmium fluoride at 25° contain 4.36 grms. CdF_2 —and in $10.8N$ - HF , 0.372 mol. per litre. Anhydrous zinc fluoride is very sparingly soluble in cold water. According to F. Kohrausch and G. Bodländer, a litre of water dissolves 0.00005 mol. of zinc fluoride at 18° ; and R. Dietz says a litre of water dissolves 16 grms. of $\text{ZnF}_2 \cdot 4\text{H}_2\text{O}$ at 18° . Zinc and cadmium fluorides are insoluble in alcohol, and in hydrochloric, nitric, and sulphuric acids, but they dissolve in the boiling menstrua; cadmium fluoride is readily soluble in dil. mineral acids. When cadmium fluoride is evaporated with sulphuric acid, anhydrous cadmium sulphate is formed. Zinc or cadmium fluoride can be reduced by hydrogen; when heated in air, or with water vap., the metal oxide is formed. H. Schulze completely converted the fluoride into oxide by heating it in a stream of oxygen. Hydrogen sulphide transforms zinc or cadmium fluoride into the metal sulphide; and with hydrogen chloride, cadmium fluoride forms cadmium chloride. When zinc or cadmium fluoride is melted with alkali carbonate, alkali fluorides, and the metal oxide are formed; zinc fluoride with thionyl chloride, furnished M. Meslens with thionyl fluoride, SOF_2 . According to H. Moissan, phosphorus tribromide converts zinc fluoride into bromide, but phosphorus trichloride has very little action, presumably because its volatility makes its mass action low.

Zinc fluoride is readily soluble in aqua ammonia, and it readily forms double salts with the alkali fluorides. R. Wagner, and H. von Helmholt prepared **ammonium zinc fluoride**, $2\text{NH}_4\text{F} \cdot \text{ZnF}_2 \cdot 2\text{H}_2\text{O}$, as a crystalline powder by the action of zinc hydroxide on a hot soln. of ammonium fluoride—ammonia is at the same time evolved. He also obtained similar results with cadmium fluoride; the product of the action is **ammonium cadmium fluoride**, $\text{NH}_4\text{F} \cdot \text{CdF}_2$ —almost insoluble in water, but soluble in boiling acids. R. Wagner made the same compound by the action of a soln. of ammonium fluoride in conc. aqua ammonia on freshly precipitated zinc oxide. R. Wagner made **sodium zinc fluoride**, $\text{NaF} \cdot \text{ZnF}_2$, from a mixture of the component salts. J. J. Berzelius, and R. Wagner obtained crystals of **potassium zinc fluoride**, $\text{KF} \cdot \text{ZnF}_2$, by evaporating a soln. of the component salts; C. Poulenc's analyses agree with $2\text{KF} \cdot \text{ZnF}_2$.

§ 12. Zinc and Cadmium Chlorides

According to H. Kopp, in his classical *Geschichte der Chemie* (Braunschweig, 1847), a mixture of zinc chloride was first described by J. R. Glauber, in his *De furnis novis philosophicis* (Amstelodami, 1648):

Oleum lapidis calaminaris is obtained by digesting calamine in strong spirit of salt, and strongly heating the solution, whereby a *phlegma* is given off, and there remains a thick oil, as unctuous as olive oil, and not specially corrosive, because the *spiritus salis* has itself been weakened by dissolving the calamine, and thereby lost its sharpness. This *oleum* must be well protected from the air, otherwise, it attracts so much air as to form a watery liquid.

F. Stromeyer¹ first described cadmium chloride in 1818.

Other methods of preparing what came to be called *butter of zinc*—*beurre de zinc*, *butyrum zinci*, *Zinkbutter*—were discovered by J. H. Pott, J. Hellot, etc.² In 1782, F. A. Gallisch noticed that zinc forms a substance resembling butter when it is exposed to the action of dephlogisticated muriatic acid—chlorine—and in 1799 J. F. Westrumb found that finely divided zinc fires spontaneously in the same gas. R. Cowper, however, in 1883, observed that while the surface of zinc is attacked by chlorine which has passed through about 8 feet of one-inch tubing closely packed with anhydrous porous calcium chloride, it is *not* attacked if the chlorine be allowed to stand some days in contact with freshly fused calcium chloride. H. Davy also noted thin strips of zinc burn in chlorine gas with a white flame, forming zinc chloride; J. J. Berzelius made the same compound by passing dry chlorine over molten zinc—the action, he says, is attended by the emission of vivid sparks; and S. Grünauer says that with well-dried chlorine, and the purest available zinc, the reaction proceeds gradually. Zinc can also be chlorinated by heating it with twice its weight of mercuric chloride (J. H. Pott, 1741); with ammonium chloride (J. Hellot, 1735); with silicon chloride (N. N. Beketoff); with lead chloride (S. Grünauer); with phosphorus oxychloride (B. Reinitzer and H. Goldschmidt); and other chlorides of the metalloids. Many methods of preparation depend upon the volatility of zinc chloride, which, when anhydrous, boils between 700° and 730°; similar observations apply to cadmium chloride. This property enables the zinc chloride to be distilled from less volatile products. If iron be present, the ferric chloride distils first. G. P. Baxter and A. B. Lamb obtained anhydrous zinc chloride by heating ammonium zinc chloride in a stream of hydrogen chloride; and G. P. Baxter and M. A. Hines obtained anhydrous cadmium chloride in a similar manner. B. H. Jacobson found that a little bromine acts as a catalytic agent in the chlorination of zinc.

Hydrated zinc chloride crystallizes from its aq. soln. obtained by dissolving the metal, oxide, or carbonate in hydrochloric acid, or by treating soln. of the chlorides of metals which are precipitated by zinc—*e.g.* cupric chloride. According to R. Dietz, an aq. soln. can be evaporated to 80 per cent. ZnCl_2 at 50° over phosphorus pentoxide. R. Engel (1886) noticed that there are conditions when the anhydrous chloride can exist in contact with its aq. soln.; for example, F. Mylius

and R. Dietz found that an 85.5 per cent. soln. at 68° crystallizes at the room temp. in about 24 hrs., furnishing octahedral or prismatic crystals of zinc chloride; and the solubility curves, Fig. 29, show that the solid phase in aq. soln. over 28° is the anhydrous chloride. Like the other chlorides of this family, the evaporation of an aq. soln. of zinc chloride is attended by hydrolytic dissociation; so that, as noted by C. F. Wenzel in 1777, by heating a sat. soln. of zinc in hydrochloric acid, a part of the acid is expelled; and, as noted by J. Davy, a mixture of zinc chloride and oxide is obtained as a residue, but V. von Czepinsky and R. Lorenz showed that the product obtained even by melting zinc chloride, still contains a considerable amount of water, hydrogen chloride, or both. J. B. A. Dumas obtained cadmium chloride by evaporating a soln. of cadmium chloride in a stream of hydrogen chloride. Both J. H. Pott, and G. Brandt distilled zinc chloride from the residue obtained by evaporating an aq. soln. of zinc chloride to dryness—similar observations apply to cadmium chloride. W. L. Hardin sublimed the cadmium salt in a combustion tube in a stream of dry carbon dioxide.

C. Matignon and F. Bourion chlorinated *zinc oxide* by heating it in a stream of chlorine mixed with sulphur chloride vap.; K. J. Bayer treated zinc oxide suspended in water with chlorine: $6\text{ZnO} + 6\text{Cl}_2 = 5\text{ZnCl}_2 + \text{Zn}(\text{ClO}_3)_2$, and heated the resulting soln. with alkali chlorides, or treated the zinc oxide and alkali chloride together with chlorine until the last of the zinc oxide is dissolved. Many impurities are not chlorinated until after the zinc, and thus remain insoluble: $3\text{ZnO} + \text{KCl} + 3\text{Cl}_2 = 3\text{ZnCl}_2 + \text{KClO}_3$. The liquid when conc. to a sp. gr. 1.9 furnishes on cooling crystals of alkali chlorate. The mother liquid now contains very little chlorate, and it is treated with hydrochloric acid and evaporated to dryness to obtain zinc chloride. K. J. Bayer claims that there is a larger yield of chlorate with zinc oxide than when lime or magnesia is used, and that there is a large demand for the by-product, zinc chloride. E. Prior obtained zinc chloride as a by-product in the chlorinating roast of *zinc sulphide* ores mixed with sodium or calcium chloride and carbon, and subsequently volatilized at a higher temp.; G. Carrara applied a similar principle to chlorinating zinc oxides, carbonates, and hydrosilicates. E. H. Wikander made anhydrous zinc chloride by conducting a mixture of hydrogen chloride and air over zinc ferrous materials at a red heat. Wessenfeld, Dicke, & Co. chlorinated zinc oxide, sulphide, or carbonate, by mixing it with a soln. of ferric chloride. The excess of ferric chloride was then decomposed in the warm soln. by a current of air.

J. F. Persoz obtained anhydrous zinc chloride, by distilling a mixture of *zinc sulphate* and calcium chloride. C. Hensgen chlorinated zinc sulphate by the action of dry hydrogen chloride at 225°–250°; and by treating a soln. of zinc sulphate with the chloride of a metal which forms a sparingly soluble sulphate. Thus, D. C. Papenguth added calcium chloride to a soln. of zinc sulphate, and evaporated the filtrate; even sodium chloride will do at a temp. below 0°, for P. B. Sadtler and W. H. Walker applied A. J. Balard's process for Glauber's salt and cooled a soln. of zinc sulphate and sodium chloride whereby Glauber's salt crystallized out and zinc chloride remained in soln. They say that nearly a 100 per cent. yield can be obtained. According to F. Kessler, sodium zinc sulphate separates at 10° from a soln. containing a mol of zinc sulphate with two mols of sodium chloride; at 0°, Glauber's salt alone separates out and zinc chloride remains in soln. F. Käppel treated roasted zinciferous pyrites with sulphuric acid containing an excess of sodium chloride. The resulting soln. of zinc and sodium chlorides was treated with hydrogen chloride or conc. hydrochloric acid, free from the precipitated salt, and neutralized with zinc. In G. P. Baxter's work on atomic weights (*q.v.*) are described methods for the preparation of zinc and cadmium halides of a high degree of purity.

The properties of zinc and cadmium chlorides.—Molten zinc chloride is a soluble refracting fluid, and it congeals to a white vitreous or porcelain-like mass, which, according to R. Lorenz,³ is more hygroscopic than phosphorus pentoxide. Molten cadmium chloride forms a white mass with a metallic lustre; according to

J. A. Wilkinson, if prepared by passing chlorine over molten cadmium, the colour is red—possibly from the presence of the colloidal metal. According to M. Gröger, the sublimed salt forms transparent mica-like plates; W. L. Hardin obtained plate-like crystals resembling mother-of-pearl; white needles have been reported; and G. Viard obtained granular crystals. O. Lehmann studied the crystals of this salt; the crystal system is probably hexagonal. R. Dietz found the anhydrous crystals formed as solid phase in aq. soln. over 28° are octahedral or prismatic. E. F. Farnau studied the **crystalloluminescence** of the zinc and cadmium halides.

According to H. C. D. Bödeker,⁴ anhydrous zinc chloride has a **specific gravity** of 2.753 (13°), while G. P. Baxter and A. B. Lamb, as a mean of five determinations, give the mean value 2.907 at 25° (water unity). For anhydrous cadmium chloride H. C. D. Bödeker gives 3.6354 (12°); F. W. Clarke, 3.655 (16.9°) and 3.938 (23°); and G. P. Baxter and M. A. Hines, as a mean of five determinations, 4.047 at 25° (water unity). R. Lorenz, H. Frei, and A. Jabs give for the sp. gr. D of molten cadmium chloride at θ between 600° and 800° , $D = 6.175 - 0.00145\theta$. Assuming the best representative sp. gr. of zinc and cadmium chlorides are respectively 2.91 and 4.05, the respective mol. vols. are 46.9 and 45.3. W. Biltz gave 45.18 for the mol. vol. of cadmium chloride. A. J. Rabinowitsch measured the sp. gr. of soln. of the last-named salt; as also the viscosity.

The reported numbers for the **melting point** of anhydrous zinc chloride vary from R. Lorenz's 5250° to K. Hachmeister's 283° . The reason for the large difference is probably due to the more or less imperfect dehydration of the salt used in the determination; for anhydrous cadmium chloride the numbers vary from L. Graetz's 538° to O. H. Weber's 590° . The best representative values may be taken as 290° for zinc chloride, and 568° for cadmium chloride. O. Ruff and W. Plato obtained a minimum in the m.p. curve of mixtures of cadmium fluoride and chloride at about 540° and 84 molar per cent. of the chloride, Fig. 28. Likewise, the **boiling point** of anhydrous zinc chloride is 730° , according to V. Meyer and F. Freyer; T. Carnelley and W. C. Williams' data ranged from 716° to 730° ; and for anhydrous cadmium chloride from 861° to 954° —O. H. Weber gives 964° . The best representative values are 730° for zinc chloride and 960° for cadmium chloride. C. Zenghelis says that zinc chloride evaporates at ordinary temp. because a piece of zinc chloride after standing over a silver plate 5 cms. away for five days produced a grey film on the metal. According to V. and C. Meyer,⁶ the **vapour density** of zinc chloride at 891° is 4.53; and at 907° , 4.61; while the value calculated for ZnCl_2 is 4.70. A. Werner determined the mol. wt. in organic solvents. E. Beckmann found the mol. wt. of zinc chloride in boiling quinoline to be virtually normal 139 when the calculated value for ZnCl_2 is 136.3; N. Castoro also found a normal value for the f.p. of urethane; R. Lespieau found high values for the f.p. of ether representing polymerization with mol. wt. 230, 280, and 540. E. Beckmann obtained a mol. wt. 185 for soln. of cadmium chloride in boiling quinoline, the calculated value for CdCl_2 is 183; L. Rügheimer, in boiling bismuth trichloride, 187.3 to 193.1 ; G. Tammann obtained abnormal values for the lowering of the vap. press. of soln. of cadmium chloride in water; J. L. R. Morgan and H. K. Benson obtained 158 for the mol. wt. of cadmium chloride in fused trihydrated lithium nitrate. A. Werner found the solubility in piperidine to be too low to enable a mol. wt. determination to be made.

FIG. 28.—Fusion Curve of Mixtures of Cadmium Fluoride and Chloride.

O. H. Weber⁷ calculated the **heat of fusion** of cadmium chloride to be 10.5 Cals. and the **heat of vaporization**, 26.0 Cals. H. V. Regnault found the **specific heat** of vitreous zinc chloride between 21° and 99° to be 0.1362; C. Helmreich gives for

cadmium chloride between 0° and 30° , 0.09362; between 0° and 50° , 0.09533; and between 0° and 70° , 0.09701. According to J. C. G. de Marignac, the sp. and mol. ht. of soln. of zinc chloride between 19° and 51° are for soln. with a mol of salt:

Mols of H_2O .	10	15	25	50	100	200
Sp. ht. .	0.6212	0.7042	0.7960	0.8842	0.9330	0.9590
Mol. ht. .	196.5	286.1	466.7	916.0	1807	3583

A. Blümcke has also measured the sp. ht. of soln. of zinc chloride, and C. Helmreich of soln. of cadmium chloride:

Per cent. $CdCl_2$.	.	.	17.12	32.15	47.65
Sp. ht. 0° to 30° .	.	.	0.83149	0.80956	0.81409
Sp. ht. 0° to 50° .	.	.	0.70187	0.69174	0.69419
Sp. ht. 0° to 70° .	.	.	0.56910	0.56367	0.56577

G. Jäger found the **heat conductivity** of water is reduced approximately 0.00473 for each per cent. of zinc chloride in soln. The heat conductivity of a 17.5 per cent. soln. of zinc chloride is 91.5 (water 100), and of a 35 per cent. soln., 83.7. W. Beetz's values for the absolute conductivities of soln. of sp. gr. 1.132 and 1.870 are respectively 0.00436 and 0.00370 between 8° and 14° ; and 0.00660 and 0.00445 between 36° and 28° .

J. Thomsen⁸ found the **heat of formation** (Zn, Cl_2) to be 97.2 Cals., and M. Berthelot, 97.2 Cals.; R. de Forcrand, 98.73 Cals.; and R. Lorenz from 428° to 608° , 95.547 Cals. V. von Czepinsky calculates the mol. ht. of formation to be 95.869 Cals. at 408° ; 96.101 Cals. at 468° ; and 185.146 Cals. at 688° ; and from J. Thomsen's value for the heat of formation, he gives the heat of formation at 408° as 95.902— Q , and at 468° , 97.59— Q , where Q denotes the unknown mol. ht. of fusion. E. E. Somermeier found the heat of dissolution of zinc in $HCl + 191.5H_2O$ to be 30.43 Cals. per gram-atom; and T. W. Richards and T. Thorvaldson, $Zn + 2(HCl, 200H_2O) = ZnCl_2.400H_2O + H_2$ to be 36.32 Cals. for dry hydrogen and 36.07 Cals. for moist hydrogen at 20° . The total energy change, U , is 36.90 Cals. at 20° ; the temp. coeff. is negative, probably -0.030 Cal. per degree. T. W. Richards and S. Tamaru found $Cd + 2(HCl, 200H_2O) = CdCl_2.400H_2O + H_2$ at 20° to be 17.23 Cals. with dry hydrogen, and 16.98 Cals. with moist hydrogen. $U = 17.81$ Cals. at 20° ; and the temp. coeff. is negative, -0.071 Cal. per degree with conc. acid, and -0.030 Cal. per degree with dil. acids. J. Thomsen also gave ($Zn, Cl_2, aq.$), 112.3 Cals.; (Cd, Cl_2), 93.2 Cals., a number in agreement with M. Berthelot's value. H. S. Taylor and G. S. J. Perrott give 93.8 Cals. for the heat of formation of cadmium chloride from its elements. J. Thomsen also gives ($Cd, Cl_2, 2aq.$), 95.49 Cals.; and for ($CdCl_2, 2H_2O$), 2.25 Cals. R. Lorenz and M. G. Fox calculate 86.8 Cals. for the heat of formation of molten cadmium chloride between 560° and 740° . The crystals of zinc chloride have a strong affinity for water, and they deliquesce rapidly in air. J. Thomsen's value for the **heat of solution** of a mol of zinc chloride in 400 mols of water at 18° is 15.63 Cals.; and for cadmium chloride, 3.01 Cals.; M. Berthelot's value for cadmium chloride at 10° is 3.0 Cals. The heat of soln. for $CdCl_2.H_2O$ is 0.625 Cal., and for what was thought to be $CdCl_2.2H_2O$, -2.28 Cals. S. U. Pickering's value for the heat of soln. of zinc chloride is 15.22 Cals. J. Thomsen's values for the **heat of dilution** of a soln. of a mol of zinc chloride in 5 mols of water until the whole soln. contains 10, 100, and 400 mols of water are respectively 1.849, 6.809, and 8.02 Cals. C. R. A. Wright and C. Thompson's values for the heat of dilution of $xZnCl_2 + 100H_2O$ to $0.25ZnCl_2 + 100H_2O$ for $x = 0.5$, 0.4 Cal. per mol; for $x = 5$, 4.8 Cals.; and for $x = 25$, 9.0 Cals. per mol. According to W. Nernst, conc. soln. of zinc chloride are *ideal* in the sense that the heat of dilution is eq. to the change of free energy on dilution. C. R. A. Wright and C. Thompson also find the heat developed in diluting $5CdCl_2 + 100H_2O$ to $0.25CdCl_2 + 100H_2O$ is 0.1 Cal. per mol. J. Thomsen also found the **heat of neutralization** $Zn(OH)_2 + 2HCl$ in very dil. soln. to be 19.881 cal., and of $Cd(OH)_2 + 2HCl$, 20.295 cal. H. Schultze⁹ found the **electrical conductivity** of solid zinc chloride at 230° to be 0.000008.

The diagram is a phase diagram for the ZnCl_2 - H_2O system. The y-axis represents Temperature in degrees Celsius, ranging from -60 to 100. The x-axis represents Grams ZnCl_2 per 100 grms. H_2O , ranging from 0 to 600. The diagram shows the following features:

- Curve V-H:** The liquidus curve, showing the boiling point of the mixture.
- Curve H-J:** The solidus curve, showing the melting point of the mixture.
- Curve A-B:** The eutectic curve, showing the melting point of the mixture.
- Point A:** The eutectic point, where the liquid mixture of ZnCl_2 and H_2O freezes into a solid mixture of ZnCl_2 and H_2O .
- Point B:** The congruent melting point of the $4\text{H}_2\text{O}$ hydrate.
- Point H:** The congruent melting point of H_2O .
- Regions:** The diagram is divided into regions for various hydrates: $4\text{H}_2\text{O}$, $3\text{H}_2\text{O}$, $2\frac{1}{2}\text{H}_2\text{O}$, $2\text{H}_2\text{O}$, and H_2O .
- Other curves:** A dashed line (P-Q-R-U) represents the liquidus for the $2\text{H}_2\text{O}$ hydrate, and a solid line (E-F) represents the liquidus for the $2\frac{1}{2}\text{H}_2\text{O}$ hydrate.

ZnCl_2 ; trihydrated zinc chloride, $\text{ZnCl}_2 \cdot 3\text{H}_2\text{O}$, now appears as a solid phase. The transition point: $\text{ZnCl}_2 \cdot 4\text{H}_2\text{O} \rightleftharpoons \text{ZnCl}_2 \cdot 3\text{H}_2\text{O} + \text{H}_2\text{O}$, is at -30° . The solubility of trihydrated zinc chloride at 0° , is 67.5 per cent., and following the curve BCD , the trihydrated salt melts at C , 6.5° , 71.6 per cent. ZnCl_2 , and falls to the eutectic D , 0° , when the solubility is 75.5 per cent. ZnCl_2 , and the solid phases are trihydrated zinc chloride and sesquihydrated zinc chloride, $\text{ZnCl}_2 \cdot 1\frac{1}{3}\text{H}_2\text{O}$, which appears as a new solid phase. A transition point appears at 26° , H in the solubility curve of the sesquihydrated salt, DFH , when the soln. contains 80.9 per cent. ZnCl_2 . A new phase zinc monohydrated chloride, $\text{ZnCl}_2 \cdot \text{H}_2\text{O}$, now appears. The solubility curve of the triquo-salt may take a course different from BCD for the solid phase at C , about 6.5° , may suffer a change; C becomes a transition point, and a new phase, hemipentahydrated zinc chloride, $\text{ZnCl}_2 \cdot 2\frac{1}{2}\text{H}_2\text{O}$, may appear, and the solubility curve of this salt is represented by CEF ; at 12.5° , E , this salt melts, and there is 75.2 per cent. of ZnCl_2 in soln.; at the eutectic 11.5° , F , 77 per cent. ZnCl_2 , there are the solid phases hemipentahydrated zinc chloride and the new phase zinc sesquihydrated chloride, $\text{ZnCl}_2 \cdot 1\frac{1}{3}\text{H}_2\text{O}$. The solubility curve of the sesquihydrated salt, FH , has a transition point at 26° , H , 80.9 per cent. ZnCl_2 when the solid phase is zinc sesquihydrated chloride, $\text{ZnCl}_2 \cdot 1\frac{1}{3}\text{H}_2\text{O}$, and the new phase monohydrated zinc chloride, $\text{ZnCl}_2 \cdot \text{H}_2\text{O}$. The solubility curve of the monohydrated chloride has a transition point, J , 26.3° , when the soln. has 81.2 per cent. of ZnCl_2 , and solid phases monohydrated zinc chloride, and the new phase, anhydrous zinc chloride ZnCl_2 , whose solubility curve, represented by JV , terminates at 262° , the m.p. of anhydrous zinc chloride:

	26°	40°	60°	80°	100°	262°
Per cent. ZnCl_2 . .	81.2	81.9	83.0	84.4	86.0	100.0

The unstable regions of the solubility curve are dotted in the diagram.

The highest hydrated salt: **tetrahydrated zinc chloride**, $\text{ZnCl}_2 \cdot 4\text{H}_2\text{O}$, was prepared by F. Mylius and R. Dietz in large prismatic crystals by cooling a 65.4 per cent. soln. below -30° . The solubility curve has been plotted, Fig. 29, from the transition point -30° down to the eutectic with ice at -62° , although undercooled soln. down to -70° have been obtained. Very hygroscopic rhombic plates, and cubic crystals of **trihydrated zinc chloride**, $\text{ZnCl}_2 \cdot 3\text{H}_2\text{O}$, resembling sodium chloride have been obtained by R. Engel by keeping a 70.5 per cent. soln. of zinc chloride at 0° for 24 hrs. The crystallization starts when the soln. has been allowed to stand a few hours. F. Mylius and R. Dietz obtained the same result by keeping a 70.5 per cent. soln. between -10° and -15° for 2 or 3 hrs. and rubbing on the vessel with a glass rod; H. C. Jones and H. P. Bassett, at -17° ; E. Lubarsky, at -21° . The m.p. is given between 4° and 7° . The range of stability and solubility is indicated in the diagram. R. Dietz made **hemipentahydrated zinc chloride**, $\text{ZnCl}_2 \cdot 2\frac{1}{2}\text{H}_2\text{O}$, in rhombic plates by cooling a 74 per cent. soln. to 0° , or a 75.2 per cent. soln. to -10° and rubbing on the bottom of the vessel with a glass rod. The crystals are stable between 6° and the m.p., 12.5° or 13° . R. Dietz made deliquescent prismatic crystals of **sesquihydrated zinc chloride**, $\text{ZnCl}_2 \cdot 1\frac{1}{2}\text{H}_2\text{O}$, by cooling a neutral 83 per cent. soln. to 0° , warming the crystalline mass to 20° , and transferring the crystals to a 81 per cent. soln. F. Mylius and R. Dietz also obtained the crystals by cooling a 83.5 per cent. soln. R. Engel made the crystals by evaporating in a desiccator over phosphorus pentoxide, the mother liquor remaining after the crystallization of a 79.9 per cent. soln. The crystals melt at 26° —according to R. Engel, the heat of the hand suffices to melt them. By mixing hydrochloric acid with a syrupy soln. of zinc chloride, R. Schindler obtained deliquescent hexagonal plates which R. Dietz showed to be **monohydrated zinc chloride**, $\text{ZnCl}_2 \cdot \text{H}_2\text{O}$; and the latter obtained similar crystals by slowly cooling a 86 per cent. neutral soln. and transferring the crystal mass to a 82 per cent. soln.; F. Mylius and R. Dietz obtained the crystals by allowing a 83.5 per cent. soln. to stand many days; and H. C. Jones and H. P. Bassett obtained the same salt by crystallization at a high temp. The range of stability shown in Fig. 29 is small—between 26° and 28° .

FIG. 30.—Solubility Curves of Cadmium Chloride.

A. Stromeyer¹¹ in 1818, and F. J. John in 1819, described a hydrate of cadmium chloride which J. J. Berzelius believed to be *dihydrated cadmium chloride*, $\text{CdCl}_2 \cdot 2\text{H}_2\text{O}$. R. Dietz believes that the so-called dihydrated salt of the older investigators is the hemipentahydrated salt, but, as K. Drucker remarks, the existence of R. Dietz's hemipentahydrated salt cannot be regarded as *über alle Zweifel*. The *heptatritahydrated cadmium chloride*, $\text{CdCl}_2 \cdot 2\frac{3}{4}\text{H}_2\text{O}$, of H. Grossmann and B. Schück is probably either the di- or hemipentahydrated salt. R. Dietz's curves of the solubility of cadmium chloride from -9° to 100° are shown in Fig. 30. It is simpler than that of zinc chloride. R. Dietz's data up to 100° , and A. Étard's from 120° to 277° , are:

Per cent. CdCl_2 . .	-9°	-5°	0°	30°	34°	40°	100°	120°
	43.6	46.2	47.4	56.3	57.4	57.5	59.5	63.0
Solid phases . .	$\text{CdCl}_2 \cdot 4\text{H}_2\text{O}$		$\rightleftharpoons \text{CdCl}_2 \cdot 2\frac{1}{2}\text{H}_2\text{O}$		$\rightleftharpoons \text{CdCl}_2 \cdot \text{H}_2\text{O}$			

and at 170° , 68.4 per cent.; at 200° , 72 per cent.; and at 270° , 77.7 per cent. CdCl_2 . At the two transition points D, -5° , and E, 34° , there are two solid phases in the former case, $\text{CdCl}_2 \cdot 4\text{H}_2\text{O}$ and $\text{CdCl}_2 \cdot 2\frac{1}{2}\text{H}_2\text{O}$; and in the latter case, $\text{CdCl}_2 \cdot 2\frac{1}{2}\text{H}_2\text{O}$ and $\text{CdCl}_2 \cdot \text{H}_2\text{O}$. The unstable extension of the solubility curve of the tetrahydrated salt AD is the dotted line DB. At B, 12.5° , the soln. has 57.3 per cent. of CdCl_2 , and here the two solid phases are $\text{CdCl}_2 \cdot 4\text{H}_2\text{O}$ and $\text{CdCl}_2 \cdot \text{H}_2\text{O}$. The unstable region in the solubility curve of the monohydrated salt is represented by the dotted line BE.

N. Worobieff reported the formation of *pentahydrated cadmium chloride*, $\text{CdCl}_2 \cdot 5\text{H}_2\text{O}$, by cooling a 50 per cent. soln. of cadmium chloride to -14° , and drying the crystals between blotting paper. He adds that the crystals melt between 21.5° and 22° . R. Dietz failed to confirm the existence of this salt, but H. Lescœur and R. Dietz have shown the conditions under which *tetrahydrated cadmium chloride*, $\text{CdCl}_2 \cdot 4\text{H}_2\text{O}$, is formed, and its solubility is indicated in Fig. 30. Some of the older reports of dihydrated cadmium chloride really apply to this salt. According to S. U. Pickering, F. von Hauer, and others, *dihydrated cadmium chloride*, $\text{CdCl}_2 \cdot 2\text{H}_2\text{O}$, is formed when soln. of cadmium chloride are evaporated at ordinary temp., and, according to N. Worobieff, when soln. are crystallized at 100° . According to R. Dietz, and K. Sudhaus, the salt is really *hemipentahydrated cadmium chloride*. The solubility curve is indicated in Fig. 30. It is transformed into monohydrated cadmium chloride at 34° (R. Dietz); at 33° to 33.72° by dilatometric measurements, or at 34.1° by electrometric measurements (E. Cohen). J. Thomsen gives its heat of formation as 95.49 Cals. and its heat of soln. in 400 mols of water at 18° is 0.76 Cal.; and, according to S. U. Pickering, its heat of soln. is 2.284 Cals. According to A. Fock, the crystals are isomorphous with dihydrated barium chloride. The crystals were once stated to be rhombic, but R. Dietz said that they are monoclinic with axial ratios $a : b : c = 0.4181 : 1 : ?$ and with $\beta = 91^\circ 27'$. According to S. U. Pickering, and E. Cohen, the evaporation of a soln. at a high temp. furnishes fine needle-like or columnar crystals of *monohydrated cadmium chloride*, $\text{CdCl}_2 \cdot \text{H}_2\text{O}$. H. Lescœur made the same salt by evaporating the mother liquid remaining after the tetrahydrated salt has crystallized out; and G. Viard, by precipitation from a soln. of cadmium chloride by the addition of a not too great excess of sulphuric acid. H. Lescœur obtained evidence of its existence from the vap. press. curves, and he says its dissociation press. is about 50 mm. at 80° , 151 mm. at 100° , and 232 mm. at 110° , and, according to G. Viard, it passes into the anhydrous salt if kept in vacuo for a long time. The heat of soln., according to S. U. Pickering, is 0.625 Cal. The solubility curve and range of stability are shown in Fig. 30.

The **specific gravities** of aq. soln. of zinc chloride have been determined by P. Kremers,¹² C. Bender, F. Kohlrausch, D. I. Mendeléeff, D. Dijken, J. H. Long, V. S. M. van der Willigen, etc. J. H. Long's data at 15° are:

Per cent. ZnCl_2 .	0.5994	2.50	4.89	10.00	20.00	29.86	40.00	58.88
Sp. gr.	1.00056	1.024	1.046	1.094	1.094	1.297	1.423	1.728

The value for the 0.5994 per cent. soln. is by D. Dijken. J. Wagner's values at 25° for N -, $\frac{1}{2}N$ -, and $\frac{1}{4}N$ -soln. are respectively 1.0590, 1.0302, and 1.0017. P. Kremers, C. A. Valsen, J. Wagner, H. Jahn, F. J. Wershoven, S. Oppenheimer, etc., have likewise measured the sp. gr. of soln. of cadmium chloride. E. Biron's percentage values, p , at $20^\circ \pm 0.03^\circ$ (water at 4° unity) are:

Per cent. CdCl_2 .	0.849	5.01	8.046	16.65	28.61	32.52	46.49	51.21
Sp. gr.	1.0062	1.0437	1.0720	1.1613	1.3090	1.3659	1.6011	1.7020

The first two values are by O. Grottrian at 18° . E. Biron's results are very well represented by the interpolation formula: $D = 0.9983 + 0.0087144p + 0.0000474p^2 + 0.000000991p^3$. F. Fouqué has measured the change in the sp. gr. of zinc chloride soln. with temp.; P. Kremers, the vol. occupied by cadmium zinc chloride soln. of different conc.; and G. Happart showed that the contraction which occurs during the soln. of solid zinc chloride, sp. gr. 2.753 (15°), to form 100 c.c. of a p per cent. soln., is: Contraction $= 0.00244(100 - p)p$; and for cadmium chloride: Contraction $= 0.00114(100 - p)p$. According to W. Ostwald, a normal soln. of zinc chloride has the sp. vol. 0.969286. M. L. Frankenheim represents the vol., v , of a soln. at θ by the expression: $v = 1 + 0.0005435\theta + 0.00001320\theta^2$, and both P. Kremers and C. Forch have measured the thermal expansion of soln. of different conc., and found for $\frac{1}{4}N$ -, N -, and $2N$ -soln. between 0° and 5° , respectively, 0.000044, 0.000118 and 0.000271; between 5° and 10° , 0.000106, 0.000173, and 0.000315; between 10° and 15° , 0.000164, 0.000228, and 0.000354; between 15° and 20° , 0.000216, 0.000279, and 0.000398; between 20° and 25° , 0.000265, 0.000323, and 0.000434; between 25° and 30° , 0.000309, 0.000367, and 0.000467; between 30° and 35° , 0.000351, 0.000410, and 0.000504; between 35° and 40° , 0.000396, 0.000447, and 0.000526.

The **viscosities** of soln. of zinc and cadmium chlorides have been measured by J. Wagner,¹³ and he finds (water unity):

Viscosity	{	ZnCl ₂	N-	$\frac{1}{2}$ N-	$\frac{1}{3}$ N-	$\frac{1}{4}$ N-
				1.1890	1.0959	1.0526	1.0238
. .	{	CdCl ₂	1.1342	1.0631	1.0310	1.0202

O. Pulvermacher also studied the viscosity of soln. of zinc chloride. According to F. Mylius and R. Dietz, the viscosity of the syrupy soln. of zinc chloride increases rapidly as the temp. falls such that at -70° , it is brittle like glass, and at the temp. of liquid air, owing to irregular contraction, numerous crazes appear, but no crystallization occurs. G. Foussereau's value for the viscosity coeff. of molten zinc chloride at 262° is 50.9, and at 301° , 34.7. The **capillary constants** of soln. of zinc and cadmium chlorides have been measured by C. A. Valson,¹⁴ E. Klupathy, M. L. Frankenheim, etc. At 15° , C. A. Valson found a soln. containing w grms. of ZnCl₂ in 100 grms. of water to ascend a height of h mm. in a tube 0.5 mm. diameter; and for CdCl₂ a height h in a tube of 0.25 mm. diameter:

w . .	0	5	10	15	20	25	30
$h(\text{ZnCl}_2)$. .	60.6	58.7	56.9	55.3	53.9	52.6	51.6
$h(\text{CdCl}_2)$. .	60.6	58.5	56.3	54.5	53.0	51.9	—

The capillary constants of molten zinc and cadmium chlorides have been measured by G. Quincke. According to S. Motylewsky, the drop-weights, W , of zinc and cadmium chlorides at their m.p. are respectively 72 and 105, where the **surface tension**, σ , is $\sigma=0.076W$; and the **specific cohesion** $a^2=26/D$, where D is the sp. gr. at the m.p. The surface tensions of soln. of zinc chloride between 0° and 25° were found by H. Sentsis to be independent of the temp. According to J. C. Graham, the **velocity of diffusion** of 3 to 5 per cent. soln. of zinc chloride against water is 0.628; and, according to P. de Heen, it is not very different for soln. between 1 and 10 per cent. conc. According to H. de Vries, the rate of diffusion in gelatin is 2.45 sq. cm. per day.

The **vapour pressures** of soln. of zinc chloride have been measured by J. Moser,¹⁵ J. Walker, G. Tammann, and H. Lescoeur, and of cadmium chloride by H. Lescoeur and G. Tammann. According to J. Moser's data, at 20.2° for w grms. of ZnCl₂ per 1000 grms. of water when $w=250$, $dp=1.44$, $dp/p=0.082$, and $dp/pw=0.00033$; and when $w=1250$, $dp=9.55$, $dp/p=0.560$, and $dp/pw=0.00045$; for cadmium chloride at 100° , G. Tammann's numbers give $w=0.5$, $dp=9.6$, $dp/p=0.0126$, and $dp/pw=0.0252$; and for $w=5$, $dp=99.0$, $dp/p=0.130$, and $dp/pw=0.0260$. H. Lescoeur found for a sat. soln. of cadmium at 20° , a vap. press. of 12.2 mm.; for CdCl₂+4.5H₂O, 11.0 mm.; for CdCl₂+3.5H₂O, 10.5 mm.; CdCl₂+1.5H₂O, 7 mm.; +1.07H₂O, 6.5 mm.; +1.01H₂O, 6.2 mm.; and +0.96 below 2 mm. This shows a significant indication of the existence of a monohydrated salt.

The **lowering of the freezing point** of dil. soln. of zinc chloride has been investigated by H. C. Jones¹⁶ and co-workers, and by W. Biltz, and the results show that J. H. van't Hoff's constant i falls from 2.91 for soln. with 0.001 mol per litre, to $i=2.49$ for soln. with 0.0819 mols per litre. H. C. Jones and co-workers, and W. Kistiakowsky obtained similar results with soln. of cadmium chloride. L. Kahlenberg and co-workers investigated the effect of cane sugar on the results. S. M. Johnston, and A. Benrath also measured the **raising of the boiling point** of water by cadmium chloride.

The **refractive indices** of soln. of zinc and cadmium chlorides have been measured by numerous investigators.¹⁷ According to C. Cheneveau, at 16° the refractive index for the sodium-line for water alone is 1.3512, and this rises from 1.3592 to 1.380 for soln. respectively with 9.39 and 30.95 per cent. of zinc chloride; and for cadmium chloride soln. at 15° , R. de Muynck found the refractive index to rise from 1.35835 to 1.47314 as the conc. of the soln. rose from 0.159 to 0.629 mol of CdCl₂ per 100 grms. of soln. According to V. S. M. van der Willigen, for soln. of zinc chloride with light of different wave-lengths at 19.5° :

Sp. gr.	A	B	C	D	E	F	G	H
1.35949	1.39690	1.39884	1.39977	1.40222	1.40532	1.40797	1.41297	1.41738
1.20930	1.37038	1.37210	1.37292	1.37515	1.37789	1.38026	1.38465	1.38845

The **dispersions** of soln. of zinc chloride with 2.0687 and 32.822 grms. per 1000

grms. of soln. are respectively $(\mu_a - \mu_\beta)/(\mu_D - 1) = 0.0307$ and 0.0305 at 16° ; and for cadmium chloride with 0.1954 and 0.3765 grm. per c.c., $\mu_a = 1.3577$ and 1.3884 respectively; $\mu_\beta = 1.3646$ and 1.3964 ; and $\mu_D = 1.3599$ and 1.3908 . According to H. Jahn, the **electromagnetic rotation** of the plane of polarization for soln. of zinc chloride of sp. gr. 1.3200 to 1.1500 (20°) is 1.1535 ; and for soln. of cadmium chloride of sp. gr. 1.081 to 1.5645 (20.5°), is 1.14 to 1.15 . According to P. D. Foote and F. L. Mohler, the **ionization potential** of zinc chloride vapour is 12.9 volts. E. J. Evans studied the **absorption spectrum** of cadmium chloride vapour. J. R. Collins measured the ultra-red absorption spectrum of aq. soln. of zinc chloride.

According to G. Fousserau,¹⁸ the **specific resistance** of solid zinc chloride, in ohms per c.c., is 0.0107×10^8 at 171° , and 2370×10^6 at 59° , and the change of resistance R with temp. is: $\log R = 13.268 - 0.07304\theta + 0.0001112\theta^2$. L. Graetz gives the **electrical conductivity** of the solid (mercury unity), 2×10^{-8} at 230° ; 5×10^{-8} at 240° ; 10×10^{-8} at 250° ; and 16×10^{-8} at 260° . M. Faraday and W. Hampe find molten zinc chloride to be a very good conductor of electricity. G. Fousserau gives $R = 31.1900 - 1646\theta + 0.0002366\theta^2$; and L. Graetz, the conductivity (mercury unity), 100×10^{-8} at 262° , and 1450×10^{-8} at 300° ; and H. S. Schultze measured the conductivity over the range from 700° to 225° , and found it to fall rapidly with temp. Expressing the results resistance, R , in ohms per c.c.:

R	700°	500°	300°	270°	260°	250°	225°
	0.460	0.104	0.00186	0.00022	0.00011	0.000026	0.000006

The conductivity of cadmium chloride, according to L. Graetz, is:

$R \times 10^8$	580°	538°	530°	500°	490°	430°	420°	370°
	1470	1140	980	100	75	22	19	7

The electromotive force of the cell $\text{Zn} \mid \text{ZnCl}_{2(\text{molten})} \mid \text{Zn}$ is $0.00013(\theta_1 - \theta_2)$, where θ_1 is greater than θ_2 . At 500° , R. Lorenz found with carbon electrodes molten zinc chloride decomposed between 1.49 – 1.50 volts, and in carbon dioxide at 467° , at 1.505 volts. When heated to 360° , A. E. Garrett found zinc and cadmium chlorides ionized the surrounding gas; and the energy necessary for the ionization of a mol of zinc chloride at 335° is 165 Cals. nearly.

Many measurements have been made of the eq. electrical conductivities of soln. of zinc and cadmium chlorides. A. Heydweiller¹⁹ found for soln. of n mols of zinc chloride per litre, and O. Grottrian, and F. J. Wershoven for cadmium chloride, at 18° :

n	0.05	0.1	0.2	0.5	1.0	2.0	3.0	4.0	9.0
$\lambda\text{-ZnCl}_2$	—	84.8	77.7	67.3	55.1	38.9	29.2	22.5	—
$\lambda\text{-CdCl}_2$	91.0	50.0	41.2	30.8	22.4	14.4	9.9	7.2	1.4

The fall in the eq. conductivity of zinc chloride with increasing conc. is in accord with the values obtained for the chlorides of magnesium and the alkaline earths, and hence the character of the ions is approximately the same. The complex ions present are therefore less than is the case with soln. of cadmium chloride where the eq. conductivity changes more rapidly with conc. H. C. Jones and co-workers gave for the mol. conductivity, μ , and the percentage degree of ionization, α , with soln. containing a mol of cadmium chloride in v litres of soln.:

v	4	8	32	128	512	2048
μ_0°	23.65	45.32	65.63	88.34	106.14	121.19
μ_{65}°	106.5	139.6	216.2	300.0	378.8	440.5
α_0°	27.8	37.4	52.2	72.9	87.6	100.0
α_{65}°	24.2	31.7	49.1	68.1	86.0	100.0

The temperature coeff. of the conductivity of zinc chloride soln. has been determined by F. Kohlrausch, J. H. Long, S. Lussana, S. Arrhenius, and H. C. Jones and co-workers; and the effect of pressure by B. Piesch, and S. Lussana. A. J. Rabino-witsch studied the anomalous ionization—i.e. the decrease in conductivity with dilution of cadmium chloride.

The **transport number** of the anions of aq. soln. of zinc chloride has been measured by F. Kohlrausch,²⁰ W. Hittorf, G. Kümmell, and J. Moser; W. Hittorf found that with soln. containing 1.3458, 2.7005, and 53.988 grms. of water per gram of cadmium chloride in cells without a diaphragm, the respective transport numbers are 0.556, 0.555, 0.565 for the anions, and 0.444, 0.445, and 0.435 for the cations; and for soln. with a 2.7736 and 332.87 grms. of water per gram of zinc chloride, W. Hittorf found the transport numbers of the anion to be respectively 1.08 and 0.700; while G. Kümmell obtained 0.603 for soln. with from 0.0013 to 0.0051 mols ZnCl_2 per litre. It therefore follows that for conc. soln. of zinc chloride, a comparatively large proportion of the zinc travels to the anode as a complex ion. G. N. Lewis and M. Randall calculated the activity coeff. of the ions of cadmium chloride. The **degree of ionization** of soln. of zinc and cadmium chlorides has been calculated by A. A. Noyes,²¹ H. C. Jones, S. Labendzinsky, etc. There is a fall from 92.1 to 74.4 per cent. ionization respectively for 0.001*N*- and 0.0819*N*-soln. of zinc chloride; and from 82.3 to 53.7 per cent. respectively for 0.366*N*- and 20.976*N*-soln. of cadmium chloride. A. Günther-Schulze studied the ionization of cadmium chloride in aq. soln.

The **electromotive force** between two soln. with *n* and *m* mols of zinc chloride per 100 mols of water was measured by C. R. A. Wright and C. Thompson²² with electrodes of zinc amalgam, and also by J. Moser. The former found when $m=24.4$, and $n=9.8$, the e.m.f.=112.0; when $m=24.4$, $n=2.04$, the e.m.f.=218.1; and when $m=3.3$, $n=2.04$, the e.m.f.=11.0; when $m=24.4$, $n=0.172$, the e.m.f.=259.0; when $m=3.3$, $n=0.172$, the e.m.f.=51.9; and when $m=0.25$, $n=0.172$, the e.m.f.=4.9. The potential of zinc in soln. of zinc chloride against a normal calomel electrode is 1.062, 1.090, and 1.104 volts respectively for N -, $\frac{1}{10}N$ -, and $\frac{1}{100}N$ -soln. of ZnCl_2 . Similar results have been obtained with soln. of cadmium chloride by C. R. A. Wright and C. Thompson. T. des Courdes, E. Bouty, A. Hagenbach, etc. The temp. coeff. as well as the electromotive force of various voltaic combinations have likewise been measured. J. Königsberger²³ found the **magnetic susceptibility** of aq. soln. of zinc and cadmium chlorides, at 22°, to be 0.50×10^{-6} (air zero) units of mass; and S. Meyer the magnetic susceptibility of powdered cadmium chloride at 18° to be -0.25×10^{-6} (air zero).

Zinc chloride is used as a preservative for wood. In 1918, 31,101,111 lbs. were used for this purpose in the United States. G. Wood²⁴ showed that sodium fluoride offers some advantages over zinc chloride, and G. M. Hunt thus summarizes the relative advantages of these two preservatives:

Solubility in water: zinc chloride is soluble in all proportions; sodium fluoride is soluble to about 4 per cent. Toxicity: zinc chloride is toxic enough to increase materially the life of wood; sodium fluoride is over twice as toxic as zinc chloride. Corrosive effect on steel: zinc chloride is somewhat corrosive, but is commonly used in steel apparatus; sodium fluoride is much less corrosive than zinc chloride. Effect on paint: zinc chloride cannot be successfully painted over; sodium fluoride does not injure paint. Convenience of shipping: zinc chloride is shipped in 50 per cent. soln. or solid, but the solid form is deliquescent and must be sealed in air-tight containers; sodium fluoride is shipped as dry powder in slack coopeage. Present cost: zinc chloride is about 4*d.* per lb.; sodium fluoride about 7½*d.* per lb.

According to H. G. Denham,²⁵ the **hydrolysis** of zinc chloride soln.: $\text{ZnCl}_2 + 2\text{H}_2\text{O} \rightleftharpoons \text{Zn}(\text{OH})_2 + 2\text{HCl}$, has not attained equilibrium in 16 days; F. L. Perrot said that the state of equilibrium is rapidly attained. With a mol of ZnCl_2 in 75 mols of water, 3.25 per cent. of the zinc chloride is hydrolyzed. W. Bein found that cadmium chloride soln. are slightly hydrolyzed at low temp., and the amount of hydrolysis increases as the temp. rises. J. H. Long found for a mol of cadmium chloride per 1.06 litres at 85°, a hydrolysis of 2.08 per cent., and M. Chanoz for $\frac{1}{2}N$ -soln., 0.05 per cent. Zinc chloride readily forms basic salts. A large number of basic zinc chlorides, or zinc oxychlorides, have been reported²⁶ by R. Schindler, R. Bunsen, G. André, R. J. Kane, etc. Writing the mol. ratio in the order $\text{ZnO} : \text{ZnCl}_2 : \text{H}_2\text{O}$, the following oxychlorides have been reported: 9:1:3;

8:1:10; 6:1:6; $5\frac{1}{2}$:1: n ; 5:1:6; 5:1:8; 9:2:12; 4:1:11; 4:1:6; 4:1:0; 3:1: x ; 3:1:5; 3:1:3; 5:2:26; 3:2:11; 1:3:1; and 1:1:1 $\frac{1}{2}$.

Zinc hydroxide or oxide is soluble in aq. soln. of a zinc salt, and when a conc. soln. is diluted with water, a basic salt is precipitated. According to A. Sordelli, water does not precipitate a basic chloride from conc. soln. of zinc chloride, but **zinc henaoxytetrachloride**, $2\text{ZnCl}_2 \cdot 11\text{ZnO}$, is precipitated from a sat. soln. of zinc oxide in one of zinc chloride. Solubility determinations of zinc oxide in aq. soln. of zinc chloride were found by A. Driot to indicate the existence of $\text{ZnCl}_2 \cdot 4\text{ZnO} \cdot 6\text{H}_2\text{O}$ and of $\text{ZnCl}_2 \cdot \text{ZnO} \cdot 1\frac{1}{2}\text{H}_2\text{O}$, both of which were isolated. The composition of these two substances does not vary with temp. The first is amorphous and loses $5\text{H}_2\text{O}$ at 200° , and the latter, which occurs in microscopic crystals, loses one H_2O at 230° , and decomposes at a higher temp. R. Schindler made **zinc enneaoxydichloride**, $\text{ZnCl}_2 \cdot 9\text{ZnO} \cdot 3\text{H}_2\text{O}$, by adding water to a syrupy soln. of zinc chloride evaporated until fumes of hydrogen chloride are evolved; and also by filtering a soln. of zinc chloride treated with ammonia insufficient for complete precipitation. R. J. Kane made it by adding potassium hydroxide to an aq. soln. of zinc chloride until it reacts alkaline. The white powder cannot be completely freed from chlorine by boiling with a soln. of potassium carbonate. It is insoluble in water; sparingly soluble in aq. ammonia; and easily dissolved by acids. G. André made **zinc octoxydichloride**, $\text{ZnCl}_2 \cdot 8\text{ZnO} \cdot 10\text{H}_2\text{O}$, by treating zinc diammino-chloride, $\text{ZnCl}_2 \cdot 2\text{NH}_3 \cdot \text{H}_2\text{O}$, with hot water. The heat of formation is 1.4 cal. R. J. Kane made **zinc hexaoxydichloride**, $\text{ZnCl}_2 \cdot 6\text{ZnO} \cdot 6\text{H}_2\text{O}$, by treating zinc monammino-chloride, $\text{Zn}(\text{NH}_3)\text{Cl}_2$, or $\text{Zn}(\text{NH}_3)_2\text{Cl}_2 \cdot \frac{1}{2}\text{H}_2\text{O}$, with water; and by adding aq. ammonia to a soln. of zinc chloride until the precipitate partially dissolves. The white powder is insoluble in water; when calcined, it loses water, and a residue is formed from which water extracts zinc chloride, and a higher oxychloride remains. G. André prepared **zinc pentaoxydichloride**, $\text{ZnCl}_2 \cdot 5\text{ZnO} \cdot 8\text{H}_2\text{O}$, by adding water to a syrupy soln. of zinc chloride. The heat of formation is 2.5 cal. F. L. Perrot made it by pouring 100 c.c. of water at 10° on 5-6 grms. of anhydrous zinc chloride; and washing the mass free from undecomposed zinc chloride. It is dried in vacuo, and then at 38° over sulphuric acid; he regarded his preparation as hexahydrate. J. Habermann obtained **zinc enneaoxytetrachloride**, $2\text{ZnCl}_2 \cdot 9\text{ZnO} \cdot 12\text{H}_2\text{O}$, as a white insoluble powder, by adding dil. aq. ammonia, with constant stirring, to a boiling conc. soln. of zinc chloride until a precipitate appears. If this compound be washed for a long time, G. André found that **zinc tetraoxydichloride**, $\text{ZnCl}_2 \cdot 4\text{ZnO} \cdot 11\text{H}_2\text{O}$, is produced; the heat of formation is 3.2 cal. If the salt $2\text{ZnCl}_2 \cdot 3\text{ZnO} \cdot 11\text{H}_2\text{O}$ is heated with alcohol, $\text{ZnCl}_2 \cdot 4\text{ZnO} \cdot 6\text{H}_2\text{O}$ is formed. This salt was also obtained by A. Driot—*vide supra*. R. Schindler made **zinc trioxydichloride**, $\text{ZnCl}_2 \cdot 3\text{ZnO} \cdot 2\text{H}_2\text{O}$, by boiling a fairly conc. soln. of zinc chloride and oxide; by adding to a soln. of zinc chloride insufficient aq. ammonia for complete precipitation, and digesting the precipitate with the mother liquid. The former process gives octahedral crystals, the latter process, a white powder. The product is slightly soluble in water, easily soluble in an aq. soln. of zinc chloride, in dil. acids, in aq. ammonia, and in a soln. of potassium hydroxide. This salt was also made by V. S. M. van der Willigen. A. Werner represented the trihydrate by the structural formula

G. André made hexagonal plates of a pentahydrate by heating a soln. of zinc chloride with zinc oxide; and by treating a soln. of zinc chloride with insufficient ammonia for complete precipitation. A. Mailhe made the pentahydrate by the action of mercuric oxide on a cold soln. of zinc chloride, and G. André gave for the heat of formation 2.6-3.0 Cals. J. Allan made crystals of **zinc diammino-trioxydichloride**, $\text{ZnCl}_2 \cdot 3\text{ZnO} \cdot 2\text{NH}_3 \cdot 4\text{H}_2\text{O}$, by adding alcohol to an ammoniacal soln. of

zinc chloride, and allowing the mixture to stand for some days. When zinc chloride is treated with lead oxide, G. André said that a **zinc lead oxychloride**, $3(\text{ZnCl}_2 \cdot 3\text{ZnO}) \cdot 2(\text{PbCl}_2 \cdot \text{PbO}) \cdot 14\text{H}_2\text{O}$, is formed; and copper oxide gives a **zinc cupric oxychloride**, $(\text{ZnCl}_2 \cdot \text{ZnO} \cdot 2\text{CuO})(\text{ZnCl}_2 \cdot 3\text{CuO})6\text{H}_2\text{O}$, but mercuric oxide does not form a double oxychloride. G. André boiled 150 grms. of fused zinc chloride, 40 grms. of zinc oxide, and 400 grms. of water with ammonium chloride and obtained **zinc pentoxytetrachloride**, $5\text{ZnO} \cdot 2\text{ZnCl}_2 \cdot 26\text{H}_2\text{O}$. He also reported **zinc trioxytetrachloride**, $3\text{ZnO} \cdot 2\text{ZnCl}_2 \cdot 11\text{H}_2\text{O}$, obtained by boiling a soln. of zinc chloride with zinc oxide and cooling the clear soln. A. Driot made **zinc monooxydichloride**, $\text{ZnCl}_2 \cdot \text{ZnO} \cdot 1\frac{1}{2}\text{H}_2\text{O}$, as indicated above. F. Ephraïm made **zinc oxyhexachloride**, $3\text{ZnCl}_2 \cdot \text{ZnO} \cdot \text{H}_2\text{O}$, by the action of a soln. of 2 mols of zinc chloride on a mol of lithium carbonate. The six-sided plates lose water when heated, and then give off vapours of zinc chloride. Water decomposes the salt with the separation of zinc hydroxide. It is soluble in dil. acids. G. André made **zinc dodecammino-oxychloride**, $2\text{ZnCl}_2 \cdot \text{ZnO} \cdot 12\text{NH}_3 \cdot 4\text{H}_2\text{O}$, or $6\text{ZnCl}_2 \cdot \text{ZnO} \cdot 12\text{NH}_3 \cdot 4\text{H}_2\text{O}$, by dissolving anhydrous zinc chloride in conc. ammonia, and evaporating the clear liquid. The heat of formation with liquid water is given as 134.58 Cals. In the absence of a systematic study in the light of the phase rule, apart from chemical analyses, there is little to show which of these salts is a chemical individual, and which a mixture. There is little doubt that several of these oxychlorides are mixtures, and the remarks with respect to the magnesium oxychlorides apply to the zinc and cadmium oxychlorides. R. de Forcrand said that G. André's products are probably addition products of zinc chloride and zinc hydroxide. G. Rousseau obtained zinc oxychlorides by heating a conc. soln. of zinc dioxide with the carbonates of the alkaline earths.

E. Sorel prepared a cement, *Sorel's cement*, by a process analogous to that employed for Sorel's magnesia cement, and it was recommended as a dental cement by G. Feichtinger in 1858; J. F. Persoz employed a soln. of zinc oxide in zinc chloride as a solvent for silk, cotton, but other vegetable fibres are not attacked. The zinc oxychlorides are also used in making paint.

F. Canzoneri, A. de Schulten, etc., have reported a number of **cadmium oxychlorides** with $\text{CdO}:\text{CdCl}_2:\text{H}_2\text{O}$, as 2:1:0; 1:1:1; and 1:1:7. E. Biron, and G. Carrara noted the formation of cadmium oxychlorides during the electrolysis of soln. of cadmium chloride. F. Canzoneri made cadmium dioxychloride, $2\text{CdO} \cdot \text{CdCl}_2$, by melting cadmium oxide and chloride, or by heating cadmium itself with an excess of the chloride. The grey powder is insoluble in water, but is slowly decomposed by that liquid into cadmium oxide and chloride. A. de Schulten made cadmium oxydichloride, $\text{CdO} \cdot \text{CdCl}_2 \cdot \text{H}_2\text{O}$, or $\text{Cd}(\text{OH})\text{Cl}$, by heating for 1 to 2 days in a sealed tube, a mixture of a soln. of cadmium chloride with calcium carbonate at 200° ; E. Tassilly, and J. Habermann, by adding dil. aq. ammonia to a well-stirred soln. of cadmium chloride. The hexagonal prisms have a sp. gr. 4.56 at 15° ; at 280° , they lose only one-tenth per cent. of water, the rest is given off at a red heat. The heat of formation given by E. Tassilly is $\text{CdCl}_{2\text{aq.}} + \text{CdO} + \text{H}_2\text{O} = 2\text{Cd}(\text{OH})\text{Cl}_{\text{aq.}} + 10.2$ Cals. A. Mailhe made a heptahydrate, $\text{CdCl}_2 \cdot \text{CdO} \cdot 7\text{H}_2\text{O}$, by adding cadmium oxide to an excess of a soln. of the chloride; and E. Tassilly, a hemihydrate, $\text{CdCl}_2 \cdot \text{CdO} \cdot \frac{1}{2}\text{H}_2\text{O}$, by the action of cadmium oxide on ammonium chloride.

Several **ammonium zinc oxychlorides** have been reported with $\text{ZnO}:\text{ZnCl}_2:\text{NH}_4\text{Cl}$ as 1:2:4; 1:3:5; 1:2:8; and 1:3:10. G. André obtained **ammonium zinc oxyoctochloride**, $4\text{NH}_4\text{Cl} \cdot 2\text{ZnCl}_2 \cdot \text{ZnO}$, from the mother liquor remaining after the separation of zinc oxychloride from a hot soln. of zinc oxide, zinc chloride, and ammonium chloride; the next crop of crystals furnished **ammonium zinc oxyhenachloride**, $5\text{NH}_4\text{Cl} \cdot 3\text{ZnCl}_2 \cdot \text{ZnO}$. Both products are decomposed by water. He also reported **ammonium zinc oxyhexadecachloride**, $10\text{NH}_4\text{Cl} \cdot 3\text{ZnCl}_2 \cdot \text{ZnO}$, and **ammonium zinc oxydodecachloride**, $8\text{NH}_4\text{Cl} \cdot 2\text{ZnCl}_2 \cdot \text{ZnO}$, with heats of formation respectively of 3.71 and 3.24 Cals. The individuality of these compounds has not been definitely established.

W. Eidmann²⁷ said that zinc chloride is soluble in *methyl alcohol*, and G. Carrara and L. d'Agostini, and W. Hampe said the same about cadmium chloride, and, added W. Hampe, the soln. is a good electrical conductor. C. A. L. de Bruyn says that at 15.5°, 100 grms. of methyl alcohol dissolve 1.71 grms. of cadmium chloride. Zinc and cadmium chlorides are soluble in *ethyl alcohol*. C. A. L. de Bruyn said that 100 grms. of ethyl alcohol at 15.5° dissolve 1.52 grms. of cadmium chloride; and H. Jahn that unit volume of an alcoholic soln. at 20° contains 0.03129 grm. of CdCl_2 , and the sp. gr. is 0.83168. T. Graham found the soln. is formed "with great facility, and when filtered has a light amber colour; it may be conc. to a very great extent without injury, and becomes so viscid when cold that it may be inverted without flowing perceptibly." He found that this soln. deposits small crystals of **zinc alcohol-chloride**, $\text{ZnCl}_2 \cdot \text{C}_2\text{H}_5\text{OH}$. Some heat is developed during the soln. of zinc chloride in alcohol; S. U. Pickering found 9.767 Cals. per mol of zinc chloride. A. Blümcke measured the sp. and mol. ht. of the alcoholic soln. of zinc chloride; W. Hittorf, G. Vicentini, and C. Cattaneo measured the electrical conductivity of soln. of zinc chloride in ethyl alcohol; G. Coffetti of cadmium chloride in methyl alcohol; and W. Hittorf, the transport numbers of the ions of zinc chloride in ethyl alcohol. E. Rimbach and O. Weber found the addition of levulose lowered the conductivity of alcoholic soln. of cadmium chloride. H. C. Jones, and A. W. Smith estimated a 6.5 per cent. ionization in a $\frac{1}{10}\text{N}$ -soln. of zinc chloride. S. Arrhenius measured the degree of ionization in methyl, ethyl, and isopropyl alcohol soln. of cadmium chloride, as well as in ether and acetone. In the partition of cadmium chloride between amyl alcohol and water, W. Herz and M. Lewy found the salt is probably polymerized in the amyl alcohol. H. Jahn found the sp. electromagnetic rotation of the plane of polarization of an alcoholic soln. of sp. gr. 0.83168 (20°) to be 1.1856. H. C. Jones and A. Campetti found the alcoholic soln. of zinc or cadmium chloride to be electro-positive towards the aq. soln.; and L. Kahlenberg gave the e.m.f. of the two combinations $\text{Zn} : \text{ZnCl}_2$ in alcohol, and in water, each against a normal electrode, as 0.910 and 0.195 volt respectively. According to L. Levi-Bianchini, methyl alcohol decomposes cadmium chloride at the critical temp. of the soln.

W. Hampe says that anhydrous zinc chloride is soluble in anhydrous *ether* and cadmium chloride insoluble. R. Lespieau measured the lowering of the f.p. of ethereal soln. of zinc chloride. W. Hampe found that conc. soln. conduct electricity, depositing zinc on the cathode; dil. soln. do not conduct so well. W. Eidmann, and W. H. Krüg and K. P. McElroy, found zinc chloride to be readily soluble in *acetone*, and cadmium chloride is slightly soluble. H. E. Patten found zinc to be deposited from acetone soln. of zinc chloride by a current of 2 volts. A. Naumann, and M. Müller have studied the chemical reactions of zinc chloride in acetone soln.—hydrogen sulphide gives a white turbidity which clears with the further passage of the gas; silver nitrate gives a white precipitate of silver chloride; potassium thiocyanate gives a white precipitate of potassium chloride; and the filtered soln. deposits prismatic crystals of $\text{ZnCl}_2 \cdot 2\text{KCl}$; with ammonium thiocyanate, a precipitate of ammonium chloride is formed. According to A. Naumann, zinc and cadmium chlorides are soluble in *ethyl acetate*; and, according to M. Gomberg, the soln. of zinc chloride dissolves zinc. N. Castoro found zinc and cadmium chlorides to be soluble in *urethane*, and he determined the mol. wt. of the dissolved salts from the lowering of the f.p. A. Werner says zinc chloride is soluble in *methyl sulphide*; A. Naumann, in *methylal* and *benzonitrile*, and, according to A. Werner, in other *aromatic nitriles*. A. Werner found zinc chloride to be soluble in *pyridine*; E. Beckmann and W. Gabel, in *quinoline*; L. Kahlenberg measured the electromotive force of soln. of zinc chloride in quinoline, pyridine, and in *aniline*. According to A. T. Lincoln, zinc chloride is readily soluble and a good conductor in *furfural*, *methyl-propylketone*, *acetophenone*, *ethyl monochloroacetate*, *ethyl acetoacetate*, *ethyl oxalate*, pyridine, and quinoline; the conductivity is feeble in *ethyl cyanoacetate*, *ethyl benzoate*, and *amyl nitrite*; there is no conductivity in *benzyl alcohol*, and *piperidine*; and the salt is insoluble in *salicylaldehyde*, *ethyl nitrate*, and *nitrobenzene*. A. T. Lincoln, also, says that cadmium chloride is insoluble or very sparingly soluble in alcohol, *furfural*, *acetophenone*, *ethyl monochloro-acetate*, *ethyl cyanacetate*, *ethyl oxalate*, *ethyl nitrate*, *amyl nitrite*, *o-nitro-toluene*, pyridine, *piperidine*, and quinoline. G. P. Baxter and M. A. Hines say cadmium chloride is insoluble in *toluene*. J. W. Klever says that zinc chloride is soluble in *glycerol*, and C. Cattaneo measured the conductivity of the soln. Z. Klemensiewicz says zinc chloride is insoluble in *antimony trichloride*.

According to H. Schulze,²⁸ zinc chloride is readily converted to zinc oxide when it is heated in **oxygen**, or better with potassium chlorate. P. Schutzenberger found that when heated to dull redness in a stream of **hydrogen**, a white deposit of zinc chloride is formed. This is not prevented by first passing the gas through glass wool, and he considers that a volatile *zinc hydrochloride*, ZnHCl , is formed. W. D. Bancroft and H. B. Weiser found that the vapours of zinc and cadmium chlorides are readily reduced when fed into the bunsen flame, and bright mirrors of the metal are deposited on a cold porcelain tube held in the flame. The metal is liable to burn again to the oxide. Zinc chloride gives a blue to bluish-green flame, and cadmium, a yellow flame; both colours are characteristic of the respective metals burning in oxygen.

A. Helfenstein found that molten zinc chloride dissolves metallic zinc—30 grms. of neutral zinc chloride, free from water and hydrogen chloride, dissolved at 700° , 0.0406 gm. of zinc more than at 290° ; and R. L. Datta and H. Sen prepared what they regarded as **zincosic chloride**, Zn_3Cl_5 , *i.e.* $\text{ZnCl} \cdot 2\text{ZnCl}_2$, by saturating fused zinc chloride with zinc. The bluish-white product is rapidly hydrolyzed by water. *Zinc subchloride* has not been prepared. R. L. Datta and H. Sen's product is probably a soln. of zinc in zinc chloride. According to H. N. Morse and H. C. Jones, when pure anhydrous cadmium chloride is heated in vacuo or in an atm. of nitrogen; the red liquid on cooling freezes to a light grey mass, and when heated again melts to a garnet-red liquid, which decomposes to cadmium chloride and the metal. The product is a powerful reducing agent—it reduces nitric acid to nitrogen oxides, and with dil. acids develops hydrogen. It has, therefore, been suggested that the product contains *cadmium subchloride*, Cd_4Cl_7 , or, as H. N. Morse and H. C. Jones suggest, a soln. of *cadmous chloride* in *cadmic chloride*; but there is a greater probability that the product is a soln. of cadmium in cadmium chloride. According to H. Brandhorst, soln. of **zinc oxide** in molten zinc chloride are good conductors of electricity.

A. Levallois found **lead sulphide** dissolves in molten zinc chloride. On account of its great affinity for **water**, anhydrous zinc chloride is used as a reagent in organic chemistry. Thus, it carbonizes wood, dehydrates alcohols—*e.g.* it forms amylene with amyl alcohol—and it saponifies fats. It forms compounds with ethylenic hydrocarbons, organic bases, etc. When zinc chloride soln. were heated for 10 hrs. in a bomb at 212° , H. W. Fischer²⁹ found a white amorphous colloid is precipitated. The action of aqua **ammonia** and hydrogen sulphide on soln. of zinc chloride resembles the action on soln. of zinc sulphate (*q.v.*). According to L. Höpfner, soln. of zinc chloride dissolve **zinc sulphite**, and this the more the greater the conc.; lead sulphite is not dissolved. C. J. J. Fox measured the solubility of **sulphur dioxide** in aq. soln. of cadmium chloride. M. C. Schuyten found that **bromine** and **iodine** displace chlorine from aq. soln. of zinc chloride on the water-bath. With **sodium molybdatodiperiodate**, $5\text{Na}_2\text{O} \cdot 12\text{MoO}_3 \cdot \text{I}_2\text{O}_5$, C. W. Blomstrand obtained a yellow precipitate. A. Grittner says the soln. of zinc chloride attacks iron—this is no doubt determined by hydrolysis. C. F. Cross and E. J. Bevan, and E. Bronnert investigated the solvent action of zinc chloride soln. on **cellulose**; and A. Leclerc, on **starch**. J. H. Long and H. Ley investigated the effect of zinc and cadmium chloride solutions on the inversion of **sugar**. G. Gore found 100 grms. of dry **silica** dust raised the temp. of 50 c.c. of a 10 per cent. soln. of zinc chloride 0.20° . J. Wagner has studied the influence of cadmium chloride and of ferrous salts on the reaction between hydrochloric acid and potassium permanganate, and J. Brown showed that in this reaction, oxygen is evolved when cadmium chloride is present; if absent, chlorine is evolved. A. A. Noyes found a $\frac{1}{2}N$ -soln. of cadmium chloride dissolved as much **lead chloride** as a $\frac{1}{10}N$ -soln. of magnesium, manganese, calcium, or zinc chloride.

According to R. Engel,³⁰ when a current of dry hydrogen chloride at ordinary temp. is passed through a soln. of zinc chloride, and pieces of metallic zinc are frequently added, as the sp. gr. approaches 2.0 (25°), crystals begin to appear

about the gas tube. The soln. is then filtered, cooled to 0° , and evaporated over phosphorus pentoxide. Rhombohedral crystals of **zinc hydrochloride**, $2\text{ZnCl}_2 \cdot \text{HCl} \cdot 2\text{H}_2\text{O}$, are formed; and if the mother liquid be treated with hydrogen chloride, crystals of $\text{ZnCl}_2 \cdot \text{HCl} \cdot 2\text{H}_2\text{O}$ are formed. J. M. Tschelzoff has studied the progressive decomposition of these two compounds with water. A. Werner regards the one as $\text{H}(\text{ZnCl}_3) \cdot 2\text{H}_2\text{O}$, and the other as $\text{H}(\text{Zn}_2\text{Cl}_5) \cdot 2\text{H}_2\text{O}$. M. Berthelot prepared what he regarded as crystals of **cadmium dihydrochloride**, $\text{CdCl}_2 \cdot 2\text{HCl} \cdot 7\text{H}_2\text{O}$, by leading a current of hydrogen chloride into a cold sat. hydrochloric acid soln. of cadmium chloride; and he gave the heat of formation: $\text{CdCl}_2 + 2\text{HCl} + 7\text{H}_2\text{O} = 40.2$ Cals. E. Cornec and G. Urbain's study of the f.p. curves of soln. of cadmium chloride in hydrochloric acid indicates the formation of $\text{CdCl}_2 \cdot \text{HCl} \cdot n\text{H}_2\text{O}$. J. Wagner has studied the viscosity, the lowering of the f.p., and the electrical properties of soln. of cadmium chloride in hydrochloric acid.

According to G. Gore,³¹ and E. C. Franklin and C. A. Kraus, zinc and cadmium chlorides are insoluble in liquid ammonia. Zinc chloride forms a number of ammino-compounds when it is exposed under various conditions to the action of ammonia; as was observed by P. Grouvelle in 1821. There is some uncertainty as to the chemical individuality of some of the alleged zinc ammino-compounds. F. Isambert passed ammonia gas over anhydrous zinc chloride, and he found that there was a copious development of heat, and the solid increased about 20 times in vol. The product is **zinc hexammino-chloride**, $\text{ZnCl}_2 \cdot 6\text{NH}_3$, and F. Isambert found the dissociation press. rose steadily from 82 to 1722 mm. as the temp. rose from 16.4° to 78.5° . B. Kuriloff, and I. Bouzat, and F. Ephraim, also measured the dissociation press. of this compound. F. Ephraim gave 57.5° for the temp. of decomposition. C. Antoine represented the vap. press., p mm., at θ° , by $\log p = 4.9445(2.4391 - 1000/t)$, where $t = \theta + 449$. F. Isambert obtained evidence of the existence of di- and tetra-ammino-chlorides as well as of the hexammino-salt. J. F. Persoz believed that a mol of ammonia is absorbed, and R. J. Kane prepared what he regarded as **zinc monammino-chloride**, $\text{ZnCl}_2 \cdot \text{NH}_3$, by melting either the di- or tetra-ammino-compounds. On cooling, an amber-yellow gummy mass is obtained, which is very slightly crystallized. According to B. Kuriloff, the dissociation press. at 216° is 6.7 mm. R. J. Kane found that the product can be distilled undecomposed at a red heat, and with water, it forms **hydrated zinc tetrammino-chloride**, and zinc oxy-chloride. R. J. Kane, and J. C. G. de Marignac made the last-named compound in talc-like crystals by cooling the soln. obtained by passing ammonia into a hot conc. soln. of zinc chloride until the precipitate first formed has redissolved; and F. Ephraim says the soln. must be sat. with ammonia gas and cooled in an atm. of ammonia. A. A. Blanchard obtained crystals of the same salt from ammoniacal soln. of zinc chloride. The compound is decomposed by water. P. P. Dehéraïn says the compound has no combined water. F. Ephraim gave 92° for the temp. of decomposition. According to B. Kuriloff, the dissociation tension at 78° is 402.2 mm. and F. Isambert measured the ammonia press. from 31° to 112.5° , and found it rose steadily from 57 mm. to 1750 mm. **Zinc diammino-chloride**, $\text{ZnCl}_2 \cdot 2\text{NH}_3$, was obtained by R. J. Kane, and by J. C. G. de Marignac by evaporating the mother liquor remaining after they had prepared the tetrammino-salt; R. J. Kane also made it by heating the tetrammino-salt to 149° ; H. Ritthausen, by dissolving zinc in a soln. of ammonium chloride aided by cupric chloride, copper, or silver; G. André, and H. Thoms prepared this salt by dissolving freshly precipitated zinc oxide in a boiling soln. of ammonium chloride; and on evaporation crystals of $\text{ZnCl}_2 \cdot 2\text{NH}_3 \cdot \frac{1}{2}\text{H}_2\text{O}$ and $\text{ZnCl}_2 \cdot 2\text{NH}_3 \cdot \frac{2}{3}\text{H}_2\text{O}$ were obtained; if ammonia be led into a hot conc. soln. of zinc chloride until the precipitate first formed re-dissolves, G. André obtained from the cooling soln. $\text{ZnCl}_2 \cdot 2\text{NH}_3 \cdot \frac{1}{4}\text{H}_2\text{O}$. R. J. Kane assigned to the crystals half a mol of water, $\text{ZnCl}_2 \cdot 2\text{NH}_3 \cdot \frac{1}{2}\text{H}_2\text{O}$. B. Kuriloff gives 43.6 mm. for the dissociation press. at 216° , and F. Isambert found a rapid rise from 96 mm. at 222° to 1021 mm. at 297° . F. Ephraim said that the temp. of decomposition is not below 200° . According to F. M. Jäger, the crystals are rhombic bipyramids with axial ratios $a:b:c$

=0.9161:1:0.9508. When heated it forms the monammino-salt. It is decomposed by water, forming an oxychloride. It can be recrystallized from its soln. in one of ammonium chloride. E. Priwoznik found crystals of this salt were formed in Leclanché's cell: $2\text{NH}_4\text{Cl} + 2\text{MnO}_2 + \text{Zn} = \text{ZnCl}_2 \cdot 2\text{NH}_3 + \text{Mn}_2\text{O}_3 + \text{H}_2\text{O}$, but G. E. Davis says the crystals have the composition $\text{Zn}(\text{OH})_2 \cdot \text{NH}_4\text{Cl}$. J. L. Davies made **hydrated zinc pentammino-chloride**, $\text{ZnCl}_2 \cdot 5\text{NH}_3 \cdot \text{H}_2\text{O}$, by dissolving zinc chloride gradually in a cold conc. soln. of ammonia, and then passing in ammonia gas. When a large precipitate has formed it is allowed to dissolve by warming the soln. On re-cooling, octahedral crystals are obtained which decompose and deliquesce in air. They are soluble in water. G. André gives the heat of formation (water solid) as 73.24 Cals.

Cadmium chloride also forms a series of ammino-compounds. According to H. Croft, if the anhydrous salt be exposed to ammonia gas, there is a rapid absorption of gas and swelling accompanied by the development of heat. The product is **cadmium hexammino-chloride**, $\text{CdCl}_2 \cdot 6\text{HN}_3$. W. R. Lang and A. Rigaut recommended the following procedure:

Three to four grams of cadmium chloride, rendered anhydrous by heating almost to the point of fusion, were placed in a tube with the neck drawn out, to allow of its being afterwards sealed at the blowpipe, and the whole immersed in solid carbonic anhydride. Dry gaseous ammonia was passed slowly into the tube, when the chloride increased in bulk largely, and, in about 2 hrs., a layer of liquid ammonia had formed on the surface of the solid compound; the tube was sealed and left for 20 hrs. It was found preferable to use the salt in small lumps, as, when in powder, the liquid failed to penetrate through the mass, even on standing for a month. The tube was then cooled to -70° and opened, the temp. cautiously raised to -30° by means of methylic chloride, and the liquid ammonia expelled.

E. Schüler obtained the same compound by passing hydrogen chloride through a cold soln. of cadmium chloride sat. with ammonia. This compound is a crystalline powder, but slightly soluble in cold water; it loses ammonia on exposure to air, and when the smell of ammonia has disappeared, the residue is the diammino-compound $\text{CdCl}_2 \cdot 2\text{NH}_3$. The hexammino-salt melts when heated and loses all its ammonia. According to W. R. Lang and A. Rigaut, the dissociation press. rises from 46 mm. at 0° to 931 mm. at 69° ; B. Kuriloff makes the dissociation press., 331 mm. at 20° ; and W. Biltz makes the dissociation temp. at one atm. press., 306° , and the heat of dissociation $\text{CdCl}_2 \cdot 6\text{NH}_3 \rightleftharpoons \text{CdCl}_2 \cdot 4\text{NH}_3 + 2\text{NH}_3$, 10.69 Cals. G. André prepared what he regarded as *cadmium pentammino-chloride*, $\text{CdCl}_2 \cdot 5\text{NH}_3$, in small transparent crystals by passing a current of gaseous ammonia into a soln. of cadmium chloride in 20 per cent. aqua ammonia kept cold at 0° . If the crystals are dried by press. between filter paper they become opaque and lose ammonia. W. R. Lang and A. Rigaut show that G. André's crystals are not $\text{CdCl}_2 \cdot 5\text{NH}_3$, but rather $\text{CdCl}_2 \cdot 6\text{NH}_3$. G. André found that if the hexammino-salt be warmed it passes into **cadmium tetrammino-chloride**, $\text{CdCl}_2 \cdot 4\text{NH}_3$. B. Kuriloff found its dissociation press. at 78° to be 1002 mm., and at 20° , 100.5 mm. W. Biltz says that 34.6° is the dissociation temp. for one atm. press. and the heat of dissociation $\text{CdCl}_2 \cdot 4\text{NH}_3 \rightleftharpoons \text{CdCl}_2 \cdot 2\text{NH}_3 + 2\text{NH}_3$ is 12.24 Cals. G. André assumes the salt is $\text{CdCl}_2 \cdot 4\text{NH}_3 \cdot \frac{1}{2}\text{H}_2\text{O}$, and he believes that by warming the hexa- or tetrammino-compound, *cadmium triammino-chloride*, $\text{CdCl}_2 \cdot 3\text{NH}_3 \cdot \frac{1}{2}\text{H}_2\text{O}$, is formed; but the evidence is unsatisfactory, for the decomposition of the tetra- or hexa-ammino-chlorides gives **cadmium diammino-chloride**, $\text{CdCl}_2 \cdot 2\text{NH}_3$. H. Croft made this compound by dissolving cadmium chloride in a warm soln. of ammonia, and cooling; the white crystalline powder contained with some cadmium hydroxide, and he therefore preferred to prepare the salt by the spontaneous evaporation of a clear soln. of cadmium chloride in an excess of ammonia. G. André made it by pouring a sat. soln. of cadmium chloride in cooled ammonia, and evaporating off the ammonia by warming. W. Kwasnik made the same salt by passing ammonia into a conc. alcoholic soln. of cadmium chloride. E. Tassilly obtained this compound from the mother liquid remaining when a soln. of cadmium chloride is partially precipitated

by ammonia, but H. Grossmann showed that this gives an impure product. W. R. Lang and A. Rigaut made it by moistening hydrated cadmium chloride with a 20 per cent. soln. of ammonia and drying the mass over lime. The white crystalline powder has no smell. W. R. Lang and A. Rigaut said that this compound is stable at 100° ; begins to decompose at about 210° , and the decomposition is not complete at 360° , the mass melts at 400° . E. Tassilly gave the heat of formation $\text{CdCl}_2 + 2\text{NH}_3 = \text{CdCl}_2 \cdot 2\text{NH}_3$ as 37.24 Cals. W. Biltz gave the heat of dissociation $\text{CdCl}_2 \cdot 2\text{NH}_3 = \text{CdCl}_2 \cdot \text{NH}_3 + \text{NH}_3 + 18.61$ Cals. B. Kuriloff said that the dissociation press. at 216° is 361.1 mm., and W. Biltz that the dissociation temp. for one atm. is 508° . W. Kwasnik obtained **cadmium monoammino-chloride**, $\text{CdCl}_2 \cdot \text{NH}_3$, by the distillation of the diammino-salt. B. Kuriloff gave the dissociation press. at 216° as 4.53 mm. and W. Biltz the dissociation temp. at one atm. press. as 611° , and the heat of dissociation, 22.88 Cals.

T. Curtius and F. Schrader³² produced **zinc hydrazine-chloride**, $\text{ZnCl}_2 \cdot 2\text{N}_2\text{H}_4$, by adding hydrazine to zinc chloride in an ammoniacal soln. H. Franzen and O. von Mayer studied the product in some detail. **Cadmium hydrazine-chloride**, $\text{CdCl}_2 \cdot 2\text{N}_2\text{H}_4$, was also prepared, as well as the hydrochlorides, $\text{ZnCl}_2 \cdot 2(\text{N}_2\text{H}_4 \cdot \text{HCl})$, $\text{ZnCl}_2 \cdot \text{N}_2\text{H}_4 \cdot \text{HCl}$, and $\text{CdCl}_2 \cdot \text{N}_2\text{H}_4 \cdot \text{HCl}$. L. Crismer, and G. Antonoff prepared **zinc hydroxylamine-chloride**, $\text{ZnCl}_2 \cdot 2\text{NH}_2\text{OH}$, and also **cadmium hydroxylamine-chloride**, $\text{CdCl}_2 \cdot 2\text{NH}_2\text{OH}$, a compound studied by H. Goldschmidt and K. L. Syngros. R. F. Weinland and F. Schlegelmilch made **zinc iodo-chloride**, $\text{ZnCl}_2 \cdot 2\text{ICl}_3 \cdot 8\text{H}_2\text{O}$.

S. Grünauer³³ made a rough determination of the m.p. of nine mixtures of zinc and ammonium chloride, and found a V-shaped curve with a eutectic at 175° for a mixture of equi-molar parts of the two salts and for a mixture of $\text{ZnCl}_2 + 3\text{NH}_4\text{Cl}$, the fusion temp. 335° , and for $11\text{ZnCl}_2 + \text{NH}_4\text{Cl}$, 290° . There is no hint of the formation of any compound at these temp.—but as already stated the experiments were not satisfactorily searching. The salt $\text{ZnCl}_2 \cdot \text{NH}_4\text{Cl}$ is obtained by the fractional crystallization of a soln. of eq. parts of zinc and ammonium chlorides; the first crop of crystals is $\text{ZnCl}_2 \cdot 3\text{NH}_4\text{Cl}$, and later, $\text{ZnCl}_2 \cdot \text{NH}_4\text{Cl}$. K. Hachmeister studied the f.p., m.p., and b.p. curves of binary mixtures of ammonium and zinc chlorides, and obtained **ammonium zinc pentachloride**, $\text{NH}_4\text{Zn}_2\text{Cl}_5$, or $2\text{ZnCl}_2 \cdot \text{NH}_4\text{Cl}$. This makes four fairly well-defined ammonium zinc chlorides, 2 : 1, 1 : 2, 1 : 3, and 1 : 4. K. Hachmeister's equilibrium diagram is shown in Fig. 31. Where A represents the region where molten zinc chloride and the vapour of ammonium chloride are in equilibrium; B, the homogeneous liquid phase; C, crystallized zinc chloride and liquid; D, crystalline double salt and liquid; E, crystalline double salt and liquid; F, crystalline ammonium chloride and melt; G, eutectic mixture of zinc chloride and double salt; and H, eutectic mixture of ammonium chloride and double salt. The regions of existence of the three double salts $\text{ZnCl}_2 : \text{NH}_4\text{Cl}$, 1 : 2, 1 : 3, and 1 : 4, are represented accordingly. P. P. Dehérain said :

FIG. 31.—Equilibrium Diagram of Mixtures of Zinc and Ammonium Chlorides.

When an ammoniacal soln. of zinc chloride, $2\text{ZnCl} \cdot \text{NH}_3$, is treated with hydrogen chloride, it deposits fine crystals of a chloro-salt with the formula $2\text{ZnCl} \cdot \text{NH}_4\text{Cl}$, sometimes in hexagonal spangles and sometimes in needle-like crystals terminated by points.

The formulæ used by P. P. Dehérain are in the old notation and correspond respectively with $\text{ZnCl}_2 \cdot \text{NH}_3$ and $\text{ZnCl}_2 \cdot \text{NH}_4\text{Cl}$ in the notation of the present day. R. J. Kane stated that on dissolving zinc mono- and tetra-ammino-chlorides in hydrochloric acid, the corresponding double salts are formed, but D. Base has shown the former gives rise to $\text{ZnCl}_2 \cdot 2\text{NH}_4\text{Cl}$, and the latter to $\text{ZnCl}_2 \cdot 3\text{NH}_4\text{Cl}$; nor could D. Base obtain different results from J. C. G. de Marignac, only $\text{ZnCl}_2 \cdot 2\text{NH}_4\text{Cl}$ and $\text{ZnCl}_2 \cdot 3\text{NH}_4\text{Cl}$ could be obtained by mixing soln. of all proportions of the component salts—zinc and ammonium chlorides. O. Hautz reported the formation of the salt $\text{ZnCl}_2 \cdot \text{NH}_4\text{Cl} \cdot 2\text{H}_2\text{O}$ from a mixed soln. of one part of ammonium chloride and two of zinc chloride, but this has not been confirmed by later work. J. I. Pierre prepared $\text{ZnCl}_2 \cdot 2\text{NH}_4\text{Cl}$ by the evaporation of a mixture of equi-molar proportions of the component salts. J. I. Pierre's work has been confirmed by C. F. Rammelsberg. The crystals separate in thin plates which, according to J. C. G. de Marignac, belong to the rhombic system and have axial ratios $a : b : c = 0.7221 : 1 : 0.5696$. The sp. gr. is 1.879, according to H. Schiff; 1.71–1.77 (10°), according to C. H. D. Bödeker; and 1.77, according to R. Romanis. R. Schindler obtained clear rectangular prisms of $\text{ZnCl}_2 \cdot 2\text{NH}_4\text{Cl} \cdot \text{H}_2\text{O}$, by evaporating a soln. of one part of zinc oxide in conc. hydrochloric acid mixed with one part of ammonium chloride, and, from time to time, replacing the acid which had evaporated. O. Hautz made the same salt in large plates by mixing two eq. of hydrochloric acid with one of zinc carbonate, then adding another eq. of the acid, and saturating the soln. with ammonia. According to O. Hautz and G. Bassayre one part of salt dissolves in one-half or two-thirds its weight of cold water with the absorption of heat, and in 0.28 part of boiling water. L. J. Thénard also made the salt by dissolving zinc hydroxide in a soln. of ammonium chloride.

J. C. G. de Marignac prepared the salt $\text{ZnCl}_2 \cdot 3\text{NH}_4\text{Cl}$ by evaporating a soln. of about two mols of ammonium chloride with one of zinc chloride. The first crop of crystals is **ammonium zinc pentachloride**, or *ammonium pentachlorozincate*, $\text{ZnCl}_2 \cdot 3\text{NH}_4\text{Cl}$, and the later crop, **ammonium zinc tetrachloride**, or *ammonium tetrachlorozincate*, $\text{ZnCl}_2 \cdot 2\text{NH}_4\text{Cl}$. P. A. Meerburg showed that with a soln. of this composition the product must always be a mixture of these two salts. The rhombic crystals have axial ratios $a : b : c = 0.7822 : 1 : 0.6915$. M. Berthelot and G. André claim to have made crystals of $\text{ZnCl}_2 \cdot 3\text{NH}_4\text{Cl} \cdot \text{H}_2\text{O}$. According to R. Kane and P. P. Dehérain, a soln. of zinc tetrammino-chloride, $\text{ZnCl}_2 \cdot 4\text{NH}_3$, in hydrochloric acid gives needle-like crystals of $\text{ZnCl}_2 \cdot 4\text{NH}_4\text{Cl}$, but, as indicated above, D. Base showed that the product is really $\text{ZnCl}_2 \cdot 3\text{NH}_4\text{Cl}$. M. Berthelot and G. André also claim to have made $\text{ZnCl}_2 \cdot 6\text{NH}_4\text{Cl} \cdot \frac{2}{3}\text{H}_2\text{O}$, but without describing the method of preparation. Of the eight ammonium zinc chlorides which have been reported, P. A. Meerburg found only two— $\text{ZnCl}_2 \cdot 2\text{NH}_4\text{Cl}$ and $\text{ZnCl}_2 \cdot 3\text{NH}_4\text{Cl}$ —were capable of existence in aq. soln. between 0° and 30° , when he applied the phase rule; he concluded in opposition to G. André, and, as already assumed by J. C. G. de Marignac, that if hydrated salts are capable of existence, it must be at low temp., not at ordinary temp. While an application of the phase rule has revealed the existence of many unsuspected compounds, these results emphasize how at the same time, the phase rule promises to eliminate from chemistry many "compounds" which are not really such.

The compositions of soln. in equilibrium with solid phases are indicated in Fig. 32 for systems at 0° , 20° , and 30° . The curves *AB*, *BC*, *CD*, and *DE* give the composition of soln. in equilibrium respectively with NH_4Cl , $\text{ZnCl}_2 \cdot 3\text{NH}_4\text{Cl}$, $\text{ZnCl}_2 \cdot 2\text{NH}_4\text{Cl}$, and anhydrous ZnCl_2 . The point *A* represents the solubility of ammonium chloride, *E* that of anhydrous zinc chloride in water (30°); at *B*, there are the two solid phases NH_4Cl and $\text{ZnCl}_2 \cdot 3\text{NH}_4\text{Cl}$; at *C*, the two solid phases $\text{ZnCl}_2 \cdot 3\text{NH}_4\text{Cl}$ and $\text{ZnCl}_2 \cdot 2\text{NH}_4\text{Cl}$; and at *D*, the two solid phases ZnCl_2 and $\text{ZnCl}_2 \cdot 2\text{NH}_4\text{Cl}$. The isotherm *ABCDE* separates the triangle into two parts—*WABCE* gives the composition of unsat. soln.; *ABCDEZY*, the composition of soln. which split into one or two solid phases. All points in the sectors *ABY*, *BCN*, *CDM*, and *DEZ* separate into a soln. whose composition is represented by a point respectively on the curves *AB*, *BC*, *CD*, and *DE*, and a solid phase NH_4Cl , $\text{ZnCl}_2 \cdot 3\text{NH}_4\text{Cl}$, $\text{ZnCl}_2 \cdot 2\text{NH}_4\text{Cl}$, and ZnCl_2 . Points in the triangles *BYN*, *CMN*, *DMZ* represent the composition of soln. which

split into a soln. represented by the points *B*, *C*, *D* respectively, and two solid phases, $\text{NH}_4\text{Cl} + \text{ZnCl}_2 \cdot 3\text{NH}_4\text{Cl}$; $\text{ZnCl}_2 \cdot 3\text{NH}_4\text{Cl} + \text{ZnCl}_2 \cdot 2\text{NH}_4\text{Cl}$; and $\text{ZnCl}_2 + \text{ZnCl}_2 \cdot 2\text{NH}_4\text{Cl}$. The points *E* for 20° and 0° are not given in the diagram.

G. C. Wittstein,³⁴ and K. von Hauer found that cadmium oxide, hydroxide, or carbonate dissolved in a soln. of ammonium chloride with the evolution of ammonia, and on evaporation, the soln. furnished crystals with very variable proportions of ammonium and cadmium chlorides. If the soln. be boiled, K. von Hauer found that crystals of **ammonium cadmium hexachloride**, $\text{CdCl}_2 \cdot 4\text{NH}_4\text{Cl}$, are formed. According to O. Lehmann, a mixed soln. of cadmium and ammonium chlorides gives a crop of mixed crystals with a little cadmium chloride, after which, A. Johnsen found that crystals of $\text{CdCl}_2 \cdot 4\text{NH}_4\text{Cl}$ are produced, while soln. richer in cadmium chloride give crystals of $\text{CdCl}_2 \cdot \text{NH}_4\text{Cl}$. The compound $\text{CdCl}_2 \cdot 2\text{NH}_4\text{Cl}$ does not appear to exist. H. Croft found that the spontaneous evaporation of a mixed soln. of equimolar parts of cadmium and ammonium chlorides gives needle-like crystals of **ammonium cadmium trichloride**, $\text{CdCl}_2 \cdot \text{NH}_4\text{Cl}$, or NH_4CdCl_3 , which, according to K. von Hauer, can be dried over sulphuric acid. G. P. Baxter and M. A. Hines purified the product by recrystallization from water. H. Grossmann prepared the same salt from a soln. obtained by boiling cadmium hydroxide with ammonium chloride. E. Rimbach made it by shaking the salt $\text{CdCl}_2 \cdot 4\text{NH}_4\text{Cl}$, with insufficient water for complete soln. at ordinary temp., the liquid was then separated from the mass of needle-like crystals which were drained on porous tiles, and then dried at 100° . K. von Hauer assumed the crystals had $\frac{1}{2}\text{H}_2\text{O}$ as water of crystallization, but after heating to 120° a number of times, the crystals are anhydrous. E. Rimbach showed that the crystals belong to the rhombic system, and have axial ratios $a : b : c = 0.6056 : 1 : 0.7992$. E. Rimbach also represents the solubility between 2.4° and 105.9° by the expression $S = 29.88 + 0.2144\theta$, and he found no decomposition within this range of temp. At 16° , 100 grms. of water dissolve 50.26 grms. of salt; at 41.2° , 63.83 grms.; and at 105.9° , 109.33 grms. According to H. Croft, the needle-like crystals of $\text{CdCl}_2 \cdot \text{NH}_4\text{Cl}$ gradually pass into rhombohedral prisms, and, according to K. von Hauer, the mother liquor, after the separation of $\text{CdCl}_2 \cdot \text{NH}_4\text{Cl}$, furnishes rhombohedral crystals of $\text{CdCl}_2 \cdot 4\text{NH}_4\text{Cl}$. Both statements, says E. Rimbach, are *unzuverlässig*; but H. L. Wells and P. T. Walden obtained crystals such as K. von Hauer described. The salt $\text{CdCl}_2 \cdot 4\text{NH}_4\text{Cl}$, or $(\text{NH}_4)_4\text{CdCl}_6$, was prepared by E. Rimbach by boiling a soln. of 17.8 grms. of cadmium chloride 36.8 grms. of ammonium chloride, and 100 grms. of water, and adding a mixture of $\text{CdCl}_2 + 4\text{NH}_4\text{Cl}$ until the soln. is sat. Crystals of $\text{CdCl}_2 \cdot 4\text{NH}_4\text{Cl}$ separate on cooling to 16° . G. André, E. Tassilly, and H. Grossmann made the same salt by the prolonged boiling of cadmium oxide or hydroxide in a soln. of ammonium chloride. According to A. Schrauf, large rhombohedral (ditrigonal) crystals are formed with the axial ratios $a : c = 1 : 1.5704$, and $\alpha = 108^\circ 59'$, and, according to A. Johnsen, isomorphous with the salt $\text{CdCl}_2 \cdot 4\text{KCl}$; and sp. gr. 2.01. A. Schrauf gives the indices of refraction as $\omega = 1.5958$, $\epsilon = 1.5961$ for the *B*-line; $\omega = 1.6038$, $\epsilon = 1.6042$ for the *D*-line; $\omega = 1.6110$, $\epsilon = 1.6114$ for the *E*-line; and $\omega = 1.6414$, $\epsilon = 1.6418$ for the *H*-line. The crystals are optically positive, and they conduct heat fairly well. E. Rimbach gives the transformation point: $\text{CdCl}_2 \cdot 4\text{NH}_4\text{Cl} = \text{CdCl}_2 \cdot \text{NH}_4\text{Cl} + 3\text{NH}_4\text{Cl}$ at -20° . Very near the cryohydric temp. this salt can be crystallized unchanged from soln. of hydrochloric acid or lithium, calcium, or magnesium chloride.

FIG. 32.—Equilibrium Curves of Solutions $\text{ZnCl}_2 - \text{NH}_4\text{Cl} - \text{H}_2\text{O}$.

K. Hachmeister studied the f.p., m.p., and b.p. curves of binary mixtures of cadmium and ammonium chlorides, and he obtained crystals of **ammonium cadmium**

pentachloride, $2\text{CdCl}_2 \cdot \text{NH}_4\text{Cl}$. This makes three fairly well defined ammonium chlorides, 2:1, 1:1, and 1:4. K. Hachmeister's results are shown in Fig. 33, where *A* represents the region where liquid cadmium chloride is in equilibrium with vap. of ammonium chloride; *B*, the homogeneous liquid phase; *C*, equilibrium between crystals of cadmium chloride and liquid; *D*, equilibrium between crystals of ammonium chloride and liquid; *E*, eutectic mixture of cadmium and ammonium chlorides; *F*, crystals of the double salt 1:2 and liquid; *G*, eutectic mixture of cadmium chloride and the double salt 1:2; *H*, crystals of the double salt 1:2 and liquid; *I*, eutectic mixture of the double salts 1:1 and 4:1; and *K*, eutectic mixture

FIG. 33.—Equilibrium Diagram of Mixtures of Cadmium and Ammonium Chlorides.

of the double salt 4:1 and ammonium chloride.

A. Benrath³⁵ noted the very small rise in the b.p. of alcohol caused by the addition of zinc and lithium chlorides. F. Ephraim obtained very hygroscopic prisms of **lithium zinc trichloride**, $\text{LiCl} \cdot \text{ZnCl}_2 \cdot 3\text{H}_2\text{O}$, or $\text{LiZnCl}_3 \cdot 3\text{H}_2\text{O}$, by dissolving a mol of lithium carbonate in an aq. soln. of two mols of zinc chloride and adding hydrochloric acid until all the lithium carbonate was dissolved. The liquid when conc. by evaporation gave crystals of the salt in question. Evaporation of the mother liquid gave an oxychloride. F. Ephraim also obtained hygroscopic prisms of $2\text{LiCl} \cdot \text{ZnCl}_2 \cdot 2\text{H}_2\text{O}$ from a soln. with the calculated amounts of the components. A soln. with six mols of lithium chloride to one of zinc chloride gave on evaporation crystals of lithium chloride and a syrupy liquid which did not crystallize at -12° , but, after standing in a desiccator for six months, gave crystals corresponding with $3\text{LiCl}_2 \cdot \text{ZnCl}_2 \cdot 10\text{H}_2\text{O}$. A. Chassevant prepared hygroscopic needle-like crystals of **lithium cadmium trichloride**, $\text{LiCl} \cdot \text{CdCl}_2 \cdot 3\frac{1}{2}\text{H}_2\text{O}$, or $\text{LiCdCl}_3 \cdot 3\frac{1}{2}\text{H}_2\text{O}$, from a soln. containing $\text{CdCl}_2 : \text{LiCl}$ in the proportions 1:2. The crystals can be dehydrated at 120° , and they are soluble in alcohol.

F. Ephraim prepared **sodium zinc tetrachloride**, $\text{ZnCl}_2 \cdot 2\text{NaCl} \cdot 3\text{H}_2\text{O}$, or $\text{Na}_2\text{ZnCl}_4 \cdot 3\text{H}_2\text{O}$, by evaporating, on a water-bath, a soln. of equi-molar parts of the component salts, or by evaporating over sulphuric acid a soln. containing twice as much zinc chloride. The crystals in the former case are acicular, and, in the latter case, small hexagonal prisms which lose all their water in vacuo, or at 100° . The crystals are decomposed on dilution with water; they are not very hygroscopic. H. C. Jones and N. Knight have measured the electrical conductivity of aq. soln.

FIG. 34.—Freezing-point Curve of Binary Mixtures of Cadmium and Sodium Chlorides.

H. Brand studied the f.p. curve of binary mixtures of cadmium and sodium chlorides. Only a single compound is formed, **sodium cadmium tetrachloride**, $2\text{NaCl} \cdot \text{CdCl}_2$, which breaks up at 425° into sodium chloride and liquid. There is a eutectic at 392° with 45 molar per cent. of sodium chloride. H. Croft prepared small crystals of **sodium cadmium tetrachloride**, $2\text{NaCl} \cdot \text{CdCl}_2 \cdot 3\text{H}_2\text{O}$, which, according to K. von Hauer, are stable in air and lose about two-thirds of their water of

crystallization at 100° , and the remainder between 150° and 160° . According to H. Croft, one part of the salt dissolves in 1.4 parts of water at 16° ; and, according to K. Sudhaus, 100 mols of water at 19.3° dissolve 3.93 mols of the double salt; 4.29 mols at 29.7° ; 4.73 mols at 40.1° ; and 5.18 mols at 54.5° . The salt is also soluble in alcohol. According to A. S. Cushman, cadmium sulphide is not precipitated from soln. of the salt by hydrogen sulphide; F. Rüdorff found that the crystals are decomposed by dialysis. K. Sudhaus investigated the equilibrium conditions for the ternary system, $\text{CdCl}_2\text{—NaCl—H}_2\text{O}$, at 19.3° , 29.7° , 40.1° , and 54.5° . Soln. in equilibrium with the three solid phases at the temp. indicated, are indicated on the portion of the triangular diagram, Fig. 35. E. Cornec and G. Urbain investigated the lowering of the f.p. of various aq. soln. of cadmium and alkali iodides and obtained results in accord with the known double salts, $\text{CdCl}_2\cdot\text{MCl}$, where M may be NH_4 , K, Na, or H.

FIG. 35.—Equilibrium Conditions of the Ternary System, $\text{CdCl}_2\text{—NaCl—H}_2\text{O}$.

J. I. Pierre, C. F. Rammelsberg, and F. Ephraim obtained **potassium zinc tetrachloride**, $2\text{KCl}\cdot\text{ZnCl}_2$, or K_2ZnCl_4 , from a mixed soln. of the component salts, and J. C. G. de Marignac obtained the same result, whichever component was in excess. A. Neumann made it by shaking an acetone soln. of zinc chloride with potassium chloride, and evaporating off the solvent. H. Schiff gives the sp. gr. 2.297; and the rhombic crystals, according to J. C. G. de Marignac, have the axial ratios $a:b:c=0.7177:1:0.5836$, and they are isomorphous with the ammonium salt. H. Steinmetz made observations on the habit of the crystals. J. I. Pierre says they dissolve in their own weight of cold water, and in all proportions in boiling water. The crystals are very deliquescent, and melt at about 200° . H. Kopp gives the sp. ht. as 0.152. H. C. Jones and K. Ota have measured the electrical conductivity of aq. soln. of the salt; C. Sandonnini, the electrical conductivity and sp. gr. of fused mixtures of the two salts; and H. C. Jones and N. Knight, the lowering of the f.p.; and S. Labendzinsky, and C. Immerwahr the potential of the salt soln. against zinc and a normal calomel electrode. R. Schindler, and F. Ephraim also reported $\text{ZnCl}_2\cdot 2\text{KCl}\cdot\text{H}_2\text{O}$, formed in small prisms by evaporating a soln. of a mol of zinc chloride with five-sixths of a mol of potassium chloride; the mother liquid, F. Ephraim adds, furnishes thick prisms of $\text{KCl}\cdot\text{ZnCl}_2\cdot 2\text{H}_2\text{O}$ belonging to the monoclinic system.

H. Brand investigated the binary system, KCl—CdCl_2 , and found two compounds, rhombic crystals of potassium cadmium trichloride, $\text{CdCl}_2\cdot\text{KCl}$, m.p. 431° , with a maximum on the f.p. curve, Fig. 36; and potassium cadmium hexachloride, $\text{CdCl}_2\cdot 4\text{KCl}$, which breaks up at 460° into KCl and liquid. The two eutectics occur at 382° and 34 molar per cent. KCl, and 390° , with 63 molar per cent. KCl. H. Brand also studied the f.p. curves of ternary mixtures of cadmium, sodium, and potassium chlorides. The compound $\text{CdCl}_2\cdot\text{KCl}$ does not form solid soln. There are three ternary eutectics, 354° , 370° , and 373° ; and six surfaces of primary crystallization.

The presence of cadmium chloride raises the temp. at which solid soln. of potassium and sodium chlorides break up into their components.

FIG. 36.—Freezing-point Curves of Binary Mixtures of Cadmium and Potassium Chlorides.

FIG. 37.—Freezing-point Curves of the Ternary System, CdCl_2 — KCl — NaCl .

F. Bourion and E. Rouyer measured the b.p. of mixed soln. of cadmium and potassium chlorides. K. Sudhaus investigated the equilibrium conditions of the ternary system, CdCl_2 — KCl — H_2O , at 19.3, 29.7°, 40.1°, and 54.5°. His results are summarized in the portion of the triangular diagram, Fig. 38, where AB represents

FIG. 38.—Equilibrium Conditions of the Ternary System, CdCl_2 — KCl — H_2O .

the soln. in equilibrium with the solid phase, $\text{CdCl}_2 \cdot 2\frac{1}{2}\text{H}_2\text{O}$, BD , with $\text{CdCl}_2 \cdot \text{KCl} \cdot \text{H}_2\text{O}$; DE , with $\text{CdCl}_2 \cdot 4\text{KCl}$; and EF , with KCl . R. Lorenz and co-workers measured the sp. gr. of fused mixtures of potassium and cadmium chlorides. K. von Hauer, and H. Croft prepared long prismatic crystals of **potassium cadmium trichloride**, $\text{KCl} \cdot \text{CdCl}_2 \cdot \text{H}_2\text{O}$ or $\text{K} \cdot \text{CdCl}_3 \cdot \text{H}_2\text{O}$, by the spontaneous evaporation of soln. of the two salts in the right proportions. According to H. Traube, the crystals are monoclinic, and lose part of their water in dry air, or over sulphuric acid, and all is lost at 100°; the crystals melt at a higher temp. and lose chlorine. The salt is very readily soluble in water without decomposition, and it may be recrystallized from this solvent. E. Rimbach found 100 grms. of water at 15.9° dissolve 36.25 grms. of the salt; at 60.6°, 68.55 grms.; and at 105.9°, 106.91 grms. K. Sudhaus found the solubility to be in mols of $\text{CdCl}_2 \cdot \text{KCl} \cdot \text{H}_2\text{O}$ per 100 mols of water:

	15.9°	19.3°	29.7°	40.1°	41.5°	54.5°	60.6°
$\text{CdCl}_2 \cdot \text{KCl} \cdot \text{H}_2\text{O}$	2.53	2.65	3.21	3.72	3.87	4.33	4.79

E. Rimbach prepared crystals of the hemihydrate, and he represents the solubility S between 105° and $2\cdot6^\circ$ by $S=22\cdot20+0\cdot2901\theta$; and he adds that the increase in solubility with temp. is greater than with the component salts alone. W. Kistiakowsky, H. C. Jones and K. Ota, and H. C. Jones and N. Knight have measured the lowering of the f.p.; and H. C. Jones and K. Ota, and C. F. Lindsay have the conductivity of soln. of this salt. According to K. von Hauer, the evaporation of the mother liquid, remaining after the separation of the preceding salt, gives rhombohedral crystals of **potassium cadmium hexachloride**, $4\text{KCl}\cdot\text{CdCl}_2$. According to E. Rimbach, if the boiling mother liquid prepared from 13·3 grms. of cadmium chloride, 31·9 grms. of potassium chloride, and 100 grms. of water, be sat. with a mixture of CdCl_2 and KCl in the molar ratio 1 : 4, and then cooled to 24° , crystals of potassium cadmium hexachloride, analogous with $4\text{NH}_4\text{Cl}\cdot\text{CdCl}_2$ are formed, belonging to the trigonal system, and having the axial ratio $a:c=1\cdot0\cdot6067$ and $\alpha=109^\circ 38'$. According to H. G. F. Schröder, the sp. gr. of the crystals is 2·5; they are stable in air, and when heated, behave like $\text{CdCl}_2\cdot\text{KCl}$. K. Sudhaus gave for the solubility of the salt, in mols of $\text{CdCl}_2\cdot4\text{KCl}$ per 100 mols of water:

	19·3°	23·6°	29·7°	40·1°	50·2°	54·5°
$\text{CdCl}_2\cdot4\text{KCl}$. . .	41·65	45·35	49·05	57·55	68·89	69·91

The decomposition of the salt by water is hindered by the presence of hydrochloric acid; and the chlorides of lithium, calcium, etc. The aq. soln. is stable between -3° and 109° . With soln. containing four litres per mol of cadmium chloride, and two litres per mol of potassium chloride at 17° , R. Varet gives the heat of formation as $(\text{CdCl}_2+2\text{KCl})=20$ cals., and $(2\text{CdCl}_2+2\text{KCl})=28$ cals. W. Kistiakowsky, and H. C. Jones and N. Knight have measured the lowering of the f.p.; H. C. Jones and K. Ota, and C. F. Lindsay, the electrical conductivity of soln. of the salt; and S. Labendzinsky, and C. Immerwahr, the electrical potential of the salt soln. against cadmium and a normal electrode. According to V. von Lang, there is a feeble positive double refraction, and A. Schrauf gives the indices of refraction $\omega=1\cdot5841$, $\epsilon=1\cdot5842$ for the B -line; $\omega=1\cdot5906$, $\epsilon=1\cdot5907$ for the D -line; $\omega=1\cdot5965$, $\epsilon=1\cdot5966$ for the E -line; and $\omega=1\cdot6208$, $\epsilon=1\cdot6210$ for the H -line. V. von Lang measured the thermal conductivity of the crystals.

R. Godefroy prepared crystals of **rubidium zinc tetrachloride**, $\text{ZnCl}_2\cdot2\text{RbCl}$, by the evaporation of a soln. of the component salts, and he also reported a series of **rubidium cadmium tetra- and tri-chlorides**, $\text{CdCl}_2\cdot2\text{RbCl}$; $\text{CdCl}_2\cdot\text{RbCl}\cdot\frac{1}{2}\text{H}_2\text{O}$; but E. Rimbach could verify only $\text{RbCl}\cdot\text{CdCl}_2$ and $4\text{RbCl}\cdot\text{CdCl}_2$ analogous with the corresponding ammonium and potassium salts. E. Rimbach made rhombic crystals of $\text{RbCl}\cdot\text{CdCl}_2$ by evaporating a soln. with the component salts in equi-molar proportions. The axial ratios are $a:b:c=0\cdot5969:1:0\cdot5244$. The salt is stable in water between 0° and 104° , and the solubility at $1\cdot2^\circ$ is 12·97 per cent.; at $14\cdot5^\circ$, 16·8 per cent.; at $41\cdot4^\circ$, 25·31 per cent.; at $57\cdot6^\circ$, 30·83 per cent.; and at $103\cdot9^\circ$, 46·62 per cent.; or the solubility S between 0° and 104° is $S=12\cdot17+0\cdot3279\theta$. The temp. coeff. is greater than is the case with the individual salts. If a boiling soln. of 2·9 grms. cadmium chloride, 32·4 grms. of rubidium chloride, and 100 grms. of water be sat. with a mixture of CdCl_2 and RbCl in the molar proportions 1 : 4, and cooled to 14° , it furnishes trigonal crystals isomorphous with the corresponding ammonium and potassium salts. The axial ratio is $a:c=1\cdot0\cdot6323$. The crystals are decomposed by water: $4\text{RbCl}\cdot\text{CdCl}_2\rightleftharpoons 3\text{RbCl}+\text{RbCdCl}_3$; the presence of hydrochloric acid or of lithium, calcium, or other chloride hinders the decomposition. Accordingly, E. Rimbach made the same salt by evaporating a soln. of the component salts with a great excess of rubidium chloride; and from a soln. in hydrochloric acid, sat. with hydrogen chloride at 60° .

H. L. Wells and G. F. Campbell prepared colourless monoclinic prisms of **cæsium zinc pentachloride**, $3\text{CsCl}\cdot\text{ZnCl}_2$, by adding zinc chloride to a conc. soln. of cæsium chloride all in the required proportions. If a larger proportion of zinc chloride is used, colourless plates of $2\text{CsCl}\cdot\text{ZnCl}_2$ are formed. The latter salt forms under a

wide range of conditions, and it can be crystallized unchanged from water. R. Godefroy prepared this salt in a similar manner in 1875, and he remarks on its extremely large solubility in water and dil. hydrochloric acid. H. L. Wells and P. T. Walden obtained small rectangular plates of **cæsium cadmium tetrachloride**, $2\text{CsCl} \cdot \text{CdCl}_2$, or Cs_2CdCl_4 , produced as a precipitate when a soln. of cadmium chloride is added to a conc. soln. of cæsium chloride; and with a soln. of 50 grms. of cæsium chloride and 3 grms. of cadmium chloride, this salt continued to be formed until the proportion of cadmium chloride was increased to 18 grms. when $\text{CdCl}_2 \cdot \text{CsCl}$ was formed as a white crystalline powder. R. Godefroy made the salt $\text{CdCl}_2 \cdot 2\text{CsCl}$ from a conc. hydrochloric acid soln. of the component salts. The salt $\text{CdCl}_2 \cdot 2\text{CsCl}$ is very sparingly soluble in soln. of cæsium chloride, a fact which explains why no cadmium salt analogous to the 3 : 1 cæsium zinc chloride could be obtained. If the attempt be made to crystallize $\text{CdCl}_2 \cdot 2\text{CsCl}$ from water, crystals of $\text{CsCl} \cdot \text{CdCl}_2$, or CsCdCl_3 , are obtained. This salt can be recrystallized from water. It is sparingly soluble in water, and especially so in conc. soln. of cadmium chloride.

O. Menge³⁶ studied the f.p. curves of binary mixtures of calcium chloride with zinc and cadmium chlorides; in the former case, the curve gives signs of a eutectic very close to the m.p. of zinc chloride; and, in the latter case, a continuous series of mixed crystals is formed although the two salts are not isomorphous. The f.p. curve here shows a minimum which C. Sandonnini placed at 545° . K. von Hauer, J. Grailich, and C. F. Rammelsberg have prepared crystals of **calcium cadmium hexachloride**, $\text{CaCl}_2 \cdot 2\text{CdCl}_2 \cdot 7\text{H}_2\text{O}$, by concentrating a mixed soln. of the component salts in the molar proportions $\text{CaCl}_2 : \text{CdCl}_2 = 3 : 4$. If the proportions are 1 : 2 or 1 : 3 the same salt crystallizes out at first, but is later followed by $\text{Ca}_2\text{CdCl}_6 \cdot 12\text{H}_2\text{O}$, or $2\text{CaCl}_2 \cdot \text{CdCl}_2 \cdot 12\text{H}_2\text{O}$. Both salts are very hygroscopic. The crystals of $\text{CaCl}_2 \cdot 2\text{CdCl}_2 \cdot 7\text{H}_2\text{O}$ are monoclinic with axial ratios $a : b : c = 1.8728 : 1 : 1.8085$, and $\beta = 105^\circ 44'$. At 100° , the salt loses a little water, but the whole of the water is expelled only at a red heat; it melts at a higher temp. and some cadmium chloride is volatilized. With soln. containing a mol of each salt in four litres of water at 17° , R. Varet gives the heat of formation $\text{CaCl}_2 + 2\text{CdCl}_2 = 30$ cals. The anhydrous salt dissolves in water with the evolution of heat, the hydrated salt with the absorption of heat; similar remarks apply to $2\text{CaCl}_2 \cdot \text{CdCl}_2 \cdot 12\text{H}_2\text{O}$. The salt $2\text{CaCl}_2 \cdot \text{CdCl}_2 \cdot 12\text{H}_2\text{O}$ melts at 100° in its water of crystallization, and loses about half its combined water at 100° , and the other half at 150° – 155° . It melts at a higher temp. with partial decomposition. The salt effloresces in vacuo over sulphuric acid. C. Sandonnini found evidence of **strontium zinc tetrachloride**, $\text{SrCl}_2 \cdot \text{ZnCl}_2$, on the f.p. curve of mixtures of zinc and strontium chlorides. The compound decomposed on melting. J. Grailich prepared **strontium cadmium hexachloride**, $\text{SrCl}_2 \cdot 2\text{CdCl}_2 \cdot 7\text{H}_2\text{O}$, by crystallization from soln. with one or two mols of cadmium chloride per mol of strontium chloride. The monoclinic crystals over sulphuric acid or calcium chloride, lose about two-sevenths of their combined water at 100° ; three-sevenths at 125° – 130° ; five-sevenths at 170° ; and all at about 180° . The salt melts at a higher temp., and some cadmium chloride is volatilized. According to W. Knight, the sp. gr. of the salt at 24° is 2.718. It is very soluble in water. H. C. Jones and N. Knight measured the lowering of the f.p. and the electrical conductivity of aq. soln., and W. Kistiakowsky, the electrode potential. C. Sandonnini found a V-shaped curve for mixtures of strontium chloride—melting at 872° —and cadmium chloride—melting at 568° —the minimum at 500° corresponded with about 54 molar per cent. of CdCl_2 . He also found that mixtures of zinc and barium chlorides furnished a f.p. curve showing the existence of **barium zinc tetrachloride**, $\text{BaCl}_2 \cdot \text{ZnCl}_2$, with the temp. of formation 470° . O. Ruff and W. Plato made observations on the m.p. of mixtures of barium and cadmium chlorides. There is a eutectic at 475° and 65 molar per cent. of cadmium chloride and a bend in the curve at about 560° and 90 molar per cent. of the cadmium salt. G. Warner prepared small deliquescent needle-like crystals of tetrahydrated barium zinc tetrachloride, $\text{BaCl}_2 \cdot \text{ZnCl}_2 \cdot 4\text{H}_2\text{O}$, of sp. gr. 2.845 (24°), by cooling a conc. soln.

of the two salts. K. von Hauer evaporated a soln. containing barium and cadmium chlorides in the mol. proportions 1 : 1, and obtained, first crystals of barium chloride, and later those of tetrahydrated **barium cadmium tetrachloride**, $\text{BaCdCl}_4 \cdot 4\text{H}_2\text{O}$, or $\text{BaCl}_2 \cdot \text{CdCl}_2 \cdot 4\text{H}_2\text{O}$; when the molar proportions are 1 : 2, the double salt $\text{BaCdCl}_4 \cdot 4\text{H}_2\text{O}$ first crystallizes out, and then follows $\text{BaCd}_2\text{Cl}_6 \cdot 5\text{H}_2\text{O}$, or $\text{BaCl}_2 \cdot 2\text{CdCl}_2 \cdot 5\text{H}_2\text{O}$; and when the proportions are 1 : 3, the last-named salt alone crystallizes from the soln. According to K. von Hauer, the salt $\text{BaCl}_2 \cdot 2\text{CdCl}_2 \cdot 5\text{H}_2\text{O}$ loses over two-fifths of its combined water very slowly at 100° , another two-fifths about 160° , and the remainder at a higher temp. At a higher temp. the salt melts, and loses some cadmium chloride by volatilization. E. Rimbach found 100 grms. of water dissolve 83.82 grms. of salt at 22.6° ; 96.62 grms. at 41.3° ; 104.25 grms. at 59.9° ; and 165–166 grms. at 107.2° ; and the solubility S at θ° between 22.6° and 107° , is $S = 40.80 + 0.1988\theta$. According to F. Rüdorff, the component salts diffuse at different rates in aq. soln. The salt $\text{BaCl}_2 \cdot \text{CdCl}_2 \cdot 4\text{H}_2\text{O}$ forms triclinic crystals with axial ratios $a : b : c = 0.8560 : 1.05067$, and $\alpha = 90^\circ 51'$, $\beta = 106^\circ 21'$, $\gamma = 89^\circ 12'$. W. Knight gives the sp. gr. 2.952 (24°). H. Töpsøe gives 2.968; mol. vol. 78.0. At 100° , it loses over half its combined water, and the remainder at 160° . According to E. Rimbach, 100 grms. of water at 22.5° dissolve 72.06 grms. of salt; at 41.4° , 88.01 grms.; at 53.4° , 101.21 grms.; at 97.8° , 163.5 grms.; and at 109.2° , 188.27 grms.; and the solubility S at θ° between 22.5° and 109° is $S = 35.78 + 0.2678\theta$. The solubility with each salt has a higher temp. coeff. than either component alone. This salt crystallizes unchanged from its aq. soln., but the component salts diffuse in aq. soln. at different rates. According to R. Varet, the heat of admixture of soln. with a mol of each component in four litres of water at 17° is $\text{CdCl}_2 + \text{BaCl}_2 = 20$ cal.; $2\text{CdCl}_2 + \text{BaCl}_2 = 32$ cal.

G. Hermann found cuprous and zinc chlorides form a eutectic, m.p. 243° , with 90 per cent. zinc chloride. Solid soln. are formed at both ends of the series. E. W. Prevost found a deposit on the brass binding screws of a Leclanché cell with the composition of *copper zinc triamminotetrachloride*, $\text{Cu}_2\text{Zn}_2(\text{NH}_3)_3\text{Cl}_4$, but there is nothing to show that this is a chemical individual. Cuprous and cadmium chlorides were found by G. Hermann to form a continuous series of solid soln. having a f.p. with a minimum at 410° and 20 per cent. cadmium chloride. A thermal effect is observed at a lower temp. reaching a maximum at 350° and 30 per cent. cadmium chloride. This indicates the formation of **cuprous cadmium hexachloride**, $4\text{CuCl} \cdot \text{CdCl}_2$. This compound is greyish-blue, and its formation from the solid soln. is promoted by light. K. von Hauer also prepared a series of salts $\text{M}_2\text{CdCl}_6 \cdot 12\text{H}_2\text{O}$, where M denotes magnesium, manganese, cobalt, or nickel; he made a **copper cadmium tetrachloride**, $\text{CuCdCl}_4 \cdot 4\text{H}_2\text{O}$, by the evaporation of an equi-molar soln. of the two salts. In aq. soln. of all these salts the properties of the component salts can be recognized, showing that the complexes are more or less resolved into their constituents in aq. soln. O. Menge studied the f.p. curves of binary mixtures of magnesium chloride with zinc and cadmium chlorides. Magnesium and cadmium chlorides are isomorphous and form a continuous series of mixed crystals; with the mixture of zinc and magnesium chlorides, there are signs of a eutectic very close to the m.p. of zinc chloride. G. Warner prepared rhombic hygroscopic prisms of **magnesium zinc tetrachloride**, $\text{MgCl}_2 \cdot \text{ZnCl}_2 \cdot 6\text{H}_2\text{O}$, analogous with the barium salt. According to J. Grailich, and C. F. Rammelsberg **magnesium cadmium hexachloride**, $\text{MgCl}_2 \cdot 2\text{CdCl}_2 \cdot 12\text{H}_2\text{O}$ or $\text{MgCd}_2\text{Cl}_6 \cdot 12\text{H}_2\text{O}$, can be obtained by evaporating a soln. of equimolar proportions or 2 : 1 parts of cadmium and magnesium chlorides; it forms rhombic crystals with axial ratios $a : b : c = 0.9130 : 1.03039$. It loses much water in vacuo or over sulphuric acid; and over half its combined water at 100° , with stronger heating the residue melts and loses hydrogen chloride. The salt may be crystallized unchanged from water. E. Rimbach found 100 grms. of water dissolve 83.86 grms. of salt at 2.4° ; 98.77 grms. at 20.8° ; 115 grms. at 45.5° ; and 189.59 at 121.8° , and the solubility S at θ° between 2.4° and 121.8° is $S = 45.98 + 0.16505\theta$; the temp. coeff. is greater than for either of the component salts. The crystals

have a positive double refraction. The refractive indices are $\omega=1.5485$, $\epsilon=1.6099$ for violet light; $\omega=1.5400$, $\epsilon=1.5901$ for bluish-green light; $\omega=1.5331$, $\epsilon=1.5769$ for yellow light; and $\omega=1.5268$, $\epsilon=1.5728$ for red light. The salt $2\text{MgCl}_2 \cdot \text{CdCl}_2 \cdot 12\text{H}_2\text{O}$ or $\text{Mg}_2\text{CdCl}_6 \cdot 12\text{H}_2\text{O}$ is formed by evaporating a soln. of two mols of magnesium chloride and one of cadmium chloride. K. von Hauer says that the presence of free hydrochloric acid hinders the crystallization of both magnesium cadmium chlorides. $\text{MgCd}_2\text{Cl}_6 \cdot 12\text{H}_2\text{O}$ loses very little water—one per cent.—at 100° .

§ 13. Zinc and Cadmium Bromides

According to C. Mentzel,¹ bromine occurs in the cadmiferous zinc ores of Silesia, and hence it has been inferred, without proof, that zinc bromide occurs in nature. A. J. Balard prepared zinc bromide, ZnBr_2 , by dissolving zinc in hydrobromic acid; hydrogen was simultaneously developed. The evaporated liquid crystallizes with difficulty. According to R. Dietz, the sat. neutral soln. at 38° to 40° gives octahedral crystals of zinc bromide. On account of hydrolysis, some oxide is formed. C. Löwig sublimed the zinc bromide from the residue. C. P. Baxter, M. A. Hines, and H. L. Frevert made cadmium bromide by dissolving cadmium in bromine water acidified with hydrobromic acid to prevent the formation of basic salts. The soln. was heated on a water-bath to drive off every trace of free bromine; filtered; and crystallized. The crystals were dried over potassium hydroxide in vacuo. W. L. Hardin prepared cadmium bromide in a similar manner, and the crystals were dried and sublimed in a stream of dry carbon dioxide while heated in a hard glass combustion tube. A. J. Balard noted that bromine water slowly dissolves zinc oxide, forming zinc bromide and bromate, but the liquid does not bleach vegetable colours. J. B. Berthelot prepared cadmium bromide by boiling cadmium and bromine water; he also passed bromine vap. over heated zinc when colourless fused zinc bromide is formed. He also noticed that cadmium in the cold does not react very well with bromine, but when heated in a stream of bromine vap. a cloud of cadmium bromide is formed. T. W. Richards and E. F. Rogers also obtained highly pure zinc bromide by dissolving purified zinc oxide in purified hydrobromic acid, and the resulting crystals were sublimed and finally heated in a stream of hydrogen bromide and nitrogen. O. W. Huntington also dissolved purified cadmium carbonate in purified hydrobromic acid, and evaporated the soln. to dryness; he heated the mass to 200° ; and then sublimed the cadmium bromide in a stream of dry carbon

dioxide in a porcelain tube. C. D. Ragland also says that cadmium bromide is prepared more conveniently by dissolving cadmium oxide in bromine water than by passing the vapour of bromine over heated cadmium. T. W. Richards and E. F. Rogers prepared highly purified zinc bromide by treating purified zinc with purified bromine in an atm. of dry carbon dioxide.

About 40 grms. of purified zinc were treated with an excess of purified bromine in a Jena glass flask which was cooled during the reaction. The red soln. was filtered in a glass funnel through asbestos, and the excess of bromine, together with any trace of iodine which might be present, was driven off by leaving the flask in a very much inclined position on a steam-bath for some time. The dil. colourless soln. was evaporated to a small bulk, and the greater part fractionally crystallized by cooling to zero. To sublime the zinc bromide, a glass adapter for conducting the current of carbon dioxide was fitted to the lower part of a platinum retort. The substance to be sublimed was contained in a small platinum crucible fitted with a wire handle, by which it could be easily raised, lowered, or removed. The adapter was so arranged that the current of gas came as closely as possible in contact with the crucible, and so that any zinc bromide which might condense in a liquid form upon the glass, and thus run the risk of taking alkali from it, must return to the crucible and be re-distilled. The sectional drawing will give a clearer idea of the arrangement (Fig. 39). Two powerful Bunsen burners supplied heat from below, impinging upon a porcelain dish which fitted closely to the bottom of the retort and protected the platinum. The gases from the flame were diverted by a large diaphragm of asbestos board. By means of this arrangement it is possible to sublime about half a gm. of zinc bromide an hour; the crystals are exceedingly beautiful, and give every evidence of great purity. Instead of being sublimed, some of the pure salt was distilled in a current of carbon dioxide. For this purpose a medium-sized tube of the hardest glass was drawn out so as to serve as a small retort, and this was encased in a larger hard glass tube, from which it was separated by several pieces of platinum foil. A platinum boat, into which was directed the drawn-out and turned-over point of the inner tube, served as the receiver. Here, again, a diagram must assist the explanation (Fig. 40). The zinc bromide thus distilled possessed a peculiarly brilliant white lustre.

FIG. 39.—The Sublimation of Zinc Bromide.

FIG. 40.—Distillation of Zinc Bromide.

W. Orloff² states that zinc bromide forms rhombic crystals with axial ratios $a:b:c=0.924:1:1.264$. The molten mass of fused zinc or cadmium bromide crystallizes on cooling. Cadmium bromide, on sublimation, gives white plates with a mother-of-pearl lustre.

C. H. D. Bödeker³ gives the **specific gravity** of zinc bromide as 3.643 (10°); T. W. Richards and E. F. Rogers, 4.219 (4°); and C. H. D. Bödeker found for cadmium bromide, 4.712–4.910 (14°); F. W. Clarke, 4.794 (19.9°); and G. P. Baxter and M. A. Hines, 5.192 at 25°, water unity at 4°. W. Biltz gave 52.43 for the mol. vol. of cadmium bromide. A. J. Rabinowitsch measured the sp. gr. and **viscosities** of soln. of zinc and cadmium bromides. According to S. Motylowsky,⁴ the drop weights W of zinc and cadmium bromides at their m.p. are respectively 44 and 87, where the **surface tension**, σ , is $\sigma=0.076W$. C. A. Valson found that for soln. with 0, 5, 10, and 35 grms. of CdBr_2 in 100 c.c. of water, the capillary height in a tube of $\frac{1}{2}$ mm. diameter was $h=60.6, 58.2, 56.0$, and 49.0 mm.

The reported numbers for the **melting point** of zinc bromide vary from the 390° of L. Graetz⁵ to the $394^\circ \pm 2.5^\circ$ of T. Carnelley. For the m.p. of cadmium bromide, T. Carnelley gave 571°; O. H. Weber, about 580°; L. Graetz, 585°; and R. Nacken, 567°. R. Nacken observed no breaks in the heating or cooling curves of cadmium

bromide. K. Mönkemeyer observed with cadmium bromide a **transformation point** between 379° and 384°; G. Hermann said at 394°. R. Nacken obtained a

FIG. 41.—Fusion Curve of Mixtures of Cadmium Bromide and Chloride.

U-shaped curve, Fig. 41, for the f.p. of mixtures of cadmium chloride—melting at 563°—and of cadmium bromide—melting at 567°—with a minimum at 551° when 60 per cent. of CdCl_2 is present. R. Dietz also obtained mixed crystals of $\text{CdCl}_2 \cdot \text{CdBr}_2 \cdot 5\text{H}_2\text{O}$. According to T. Carnelley and W. C. Williams, the **boiling point** of zinc bromide lies between 695° and 699°; V. Meyer and F. Freyer give 642.0 to 652.4°; V. von Czepinsky, 670° to 680°; W. Hampe, 697°; the b.p. of cadmium bromide is 806° to 812°, according to T. Carnelley and W. C. Williams, and 963°, according to O. H. Weber. The **vapour density** of cadmium bromide found by V. and C. Meyer is 9.25 between 914° and 923°—the calculated value for CdBr_2 is 9.40. According to G. Tammann,⁶ the mol. wt. of cadmium bromide, calculated from the lowering of the

vap. press. of aq. soln., is abnormal.

Determinations of the **molecular weight** of zinc and cadmium bromides in organic solvents have been made. E. Beckmann found from the effect of zinc bromide on the b.p. of quinoline, a mol. wt. of 222; the calculated value for ZnBr_2 is 235.3; and from the b.p. cadmium bromide, 271; when the calculated value is 272.3. A. Werner found that by increasing the conc. of a soln. of cadmium bromide in piperidine from 2.06 to 9.47 per cent., the mol. wt. rose from 280 to 329.

According to W. Hallwachs,⁷ the coeff. of **cubical expansion** of a 35.84 per cent. soln. of cadmium bromide is 0.000046. According to C. Helmreich, the **specific heat** of cadmium bromide from 0° to 30° is 0.06561; from 0° to 50°, 0.06690; and from 0° to 70°, 0.06809. C. Helmreich gives for the sp. ht. C and mol. ht. C' of 16.13 and 41.98 per cent. soln. of cadmium bromide from 0°–30°, respectively $C=0.84123$, $C'=24.60$, and $C=0.60533$, $C'=21.64$; and from 0°–70°, $C=0.83357$, $C'=5.99$; and $C=0.60204$, $C'=17.99$. O. H. Weber's value for the heat of fusion of cadmium bromide is 5.0 to 5.2 Cals. G. G. Person gives for the **latent heat of fusion** of a mol of zinc bromide 1.83 Cals.; V. von Czepinsky, 1.91 to 1.98 Cals.

The **heat of formation** of zinc bromide is 75.93 Cals., according to J. Thomsen;⁸ 85.13 Cals., according to R. de Forcrand; and 87.2 Cals., according to M. Berthelot. M. Herschkowitsch gives for the soln. of cadmium in bromine, 77.46 Cals.; J. Thomsen, 76.3; W. Nernst, 77.3. R. Lorenz and M. G. Fox give for the change of free energy in the formation of molten cadmium bromide, at θ° , between 580° and 720°, $W=1.045-0.000742(\theta-580)$, and by substituting this value of W in J. W. Gibbs and H. von Helmholtz's formula, $Qp=23046n(W-TdW/dT)$, the thermal value of the reaction can be computed. V. von Czepinsky gives for the heat of formation of zinc bromide, calculated from the free and bound energy, 76.544 Cals. at 360°; 80.119 Cals. at 390°; 89.597 Cals. at 460°; 96.944 Cals. at 530°; and 141.124 Cals. at 460°. J. Thomsen found the **heat of solution** of a mol of ZnBr_2 in 400 mols of water, to be 17.03 Cals.; and for CdBr_2 , 0.76 Cal.

The **solubility** of zinc bromide in water has been determined by A. Étard,⁹ R. Dietz, etc. R. Dietz's data show the percentage composition or the number of grams of ZnBr_2 in 100 grms. of soln.:

	-15°	-10°	-8°	0°	15°	30°	35°	40°	80°	100°
ZnBr_2	77.1	78.45	79.06	79.55	80.7	84.08	85.4	85.57	86.57	87.05
Solid phases	$\text{ZnBr}_2 \cdot 3\text{H}_2\text{O}$			$\text{ZnBr}_2 \cdot 2\text{H}_2\text{O}$				ZnBr_2		

At the transition points -8°, B , Fig. 42, and 35°, D , Fig. 42, there are two solid phases. The unstable regions BC and DE have been realized. At the higher temp. the hydrate with the smaller proportion of water of crystallization becomes the more stable. H. Lescœur obtained indications of **monohydrated zinc bromide**,

$\text{ZnBr}_2 \cdot \text{H}_2\text{O}$, from his measurements of the vap. press. R. Dietz obtained rhombic plates of **dihydrated zinc bromide**, $\text{ZnBr}_2 \cdot 2\text{H}_2\text{O}$, by cooling an 86 per cent. soln. of neutral zinc bromide to 0° . The hydrate melts at 37° to a clear fluid. R. Dietz obtained prismatic crystals of **trihydrated zinc bromide**, $\text{ZnBr}_2 \cdot 3\text{H}_2\text{O}$, by cooling an 80 per cent. neutral soln. of zinc bromide to -25° ; and E. Lubarsky obtained it by seeding with crystals of trihydrated zinc chloride. The crystals melt at -5° , according to R. Dietz, or at -2° to -3° , according to E. Lubarsky, below which "it is possible another hydrate is formed." Both salts are very deliquescent, and their solubility and range of stability are indicated in Fig. 42.

R. Dietz, and A. Étard have also partially explored the solubility curves of cadmium bromide—the latter at temp. above 100° , the former below 100° :

	0°	18°	30°	36°	60°	100°	155°	215°	245°
CdBr_2 . . .	37.92	48.90	56.90	60.40	61.10	61.63	63.7	69.9	71.5
Solid phases . .	$\text{CdBr}_2 \cdot 4\text{H}_2\text{O}$				$\text{CdBr}_2 \cdot \text{H}_2\text{O}$				

At the transition point at 36° there are the two solid phases, $\text{CdBr}_2 \cdot 4\text{H}_2\text{O}$ and $\text{CdBr}_2 \cdot \text{H}_2\text{O}$. The unstable $\text{CdBr}_2 \cdot \text{H}_2\text{O}$ at 35° with 60.3 per cent. of CdBr_2 has been isolated. According to R. Dietz, cadmium bromide forms mono- and tetrahydrated salts. H. Lescœur's vap. press. measurements confirm the existence of the **monohydrated cadmium bromide**, $\text{CdBr}_2 \cdot \text{H}_2\text{O}$. Its range of stability and solubility are indicated in the preceding table, when the transition point is near 36° ; below this temp., **tetrahydrated cadmium bromide**, $\text{CdBr}_2 \cdot 4\text{H}_2\text{O}$, is the stable phase. H. Lescœur has studied the vap. press. curve; J. Thomsen found the heat of formation $\text{CdBr}_2 + 4\text{H}_2\text{O} = 77.73$ Cals., and the heat of soln. in 600 mols of water, -7.3 Cals. J. M. Eder reports that one part of the salt dissolves in 0.94 part of water, 3.4 parts of absolute alcohol, in 250 parts of ether (sp. gr. 0.729), and in 16 parts of alcoholic ether.

The **specific gravity** of aq. soln. of zinc bromide has been determined by P. Kremers;¹⁰ and of cadmium bromide by P. Kremers, C. A. Valson, O. Grotrian, F. J. Wershoven, and many others. P. Kremers gives for the sp. gr. of soln. with w grms. of CdBr_2 per 100 grms. of water at 19.5° :

w . . .	20.6	42.6	91.4	112.7	150.3	211.1	224.7	318.3
Sp. gr. . .	1.1715	1.3270	1.6101	1.7190	1.8797	2.1095	2.1441	2.3914

The following is a selection from O. Grotrian's and F. J. Wershoven's data for cadmium bromide at 18° :

Per cent. CdBr_2	0.0324	0.506	0.013	5.07	10.10	20.11	29.95	42.99
Sp. gr. . .	0.9990	1.0031	1.0075	1.0437	1.0916	1.2004	1.3288	1.5464

P. Kremers has also calculated the increase in volume which occurs during the dissolution of the salts, and also the effect of variations of temp. on the vol. of the soln. With 19.9, 67.5, and 189.2 mols of ZnBr_2 per 100 parts of water (vol. of water at 19.5° unity), the respective vol. at 0° are 0.99419, 0.98980, and 0.98840; and at 100° , 1.05011, 1.05640, and 1.05456. Similarly for cadmium bromide, for $n=24.3$, 44.5, and 68.1 the respective vol. at 0° are 0.99426, 0.99226, 1.00000; and at 100° , 1.04665, 1.04942, and 1.05157. These numbers show that the coeff. of expansion of soln. of these salts increases with increasing conc., and with a falling temp. The lowering of the **vapour pressures** of soln. of 0.5 and 4.0 mols of cadmium

FIG. 42.—Solubility Curves of Zinc Bromide.

bromide in a kgrm. of water at 100°, are respectively 8.6 and 80 mm., and H. C. Jones and V. J. Chambers' values¹¹ for the lowering of the f.p. of soln. of the same salt show that the degree of ionization falls from 0.93 to 0.36 as the conc. of the soln. increase from 0.00125 to 0.1124 mols CdBr₂ per litre; and that with conc. soln. the ionization is not the simple process symbolized $\text{CdBr}_2 \rightleftharpoons \text{Cd}^{++} + 2\text{Br}^-$, for complex ions are probably present.

The **indices of refraction** of zinc bromide soln. have been measured by P. Kremers¹² at 15° for soln. of sp. gr. 1.3371, 1.7190, and 2.1095 at 19.5° (water at that temp. unity), and the respective values are 1.3881, 1.4446, and 1.5002; and likewise for soln. of cadmium chloride of sp. gr. 1.3310 and 1.5951 (19.5°) the respective indices of refraction are 1.3814 (14°) and 1.4199 (16°). C. Bender gives for a 4*N*-soln. of cadmium bromide at 15°, $\mu(H_a) = 1.39574$ (19.7°); $\mu(D) = 1.39835$ (20.2°); $\mu(H_\beta) = 1.40484$ (19.9°); and $\mu(H_\gamma) = 1.40996$ (20°). Values have also been reported by H. Jahn, W. Hallwachs, and M. le Blanc and P. Rohland. The sp. **electromagnetic rotation** of the plane of polarization of soln. of cadmium bromide of sp. gr. 1.1628 to 1.3312 (20°) is 1.3044. Analogous results by J. Forchheimer showed that the mol. rotation of cadmium bromide is independent of the conc. and of the degree of ionization of the soln. According to J. A. Wilkinson, cadmium bromide gives a yellowish-white fluorescence, a faint **phosphorescence**, and a weak **thermoluminescence**. C. Sheard and C. S. Morris found that the **emission spectrum** of zinc bromide has an absorption band between 5550 and 5150. E. J. Evans studied the **absorption spectrum** of cadmium bromide vap.

According to F. Braun,¹³ anhydrous solid zinc bromide does not **conduct electricity** electrolytically; W. Hampe says that when solid it is a non-conductor, but when fused a good conductor; and V. von Czepinsky said that the fused anhydrous salt is a better conductor than the fused hydrated salt. L. Graetz's values for the conductivity *K* (mercury unity) are:

$K \times 10^8$	460°	440°	420°	400°	390°	380°	360°	340°	320°
	1000	820	650	504	430	365	250	160	59

Similarly for cadmium bromide:

$K \times 10^8$	620°	600°	590°	585°	580°	570°	560°	530°	510°
	302	288	283	280	235	120	50	7	2.8

There is therefore no abrupt break with zinc bromide in passing from the molten to the solid state; and there is a very faint break with cadmium bromide. The polarization during the electrolysis of fused zinc chloride with rise of temp. falls the more the nearer the b.p., a phenomenon which V. von Czepinsky attributes to the possible depolarizing action of the anode gases diffusing to the cathode more rapidly the higher the temp. According to C. C. Garrard, the decomposition potential of the molten salt is 1.21 volts at 504° in an atm. of carbon dioxide. O. H. Weber gives the e.m.f. of the cell $\text{Cd} | \text{CdBr}_2 | \text{Br}$ at a temp. θ between 610° and 780° as $1.1319 - 0.000486(\theta - 610)$ volts; and V. von Czepinsky, for the cell $\text{Zn} | \text{ZnBr}_2 | \text{PbBr}_2 | \text{Pb}$, 0.2286 volt at 434°, and 0.1418 volt at 673°. G. C. Schmidt and W. Hechler said that the vap. is also a good conductor, and A. E. Garrett and R. S. Willows, that the molten salt appears to ionize the surrounding atm. J. H. Long's values for the eq. **conductivities** of soln. with a mol of $\frac{1}{2}\text{ZnBr}_2$ per litre, and O. Grotrian and F. J. Wershoven's values for $\frac{1}{2}\text{CdBr}_2$ per litre at 18°, are:

<i>N</i> .	0.0001	0.002	0.01	0.05	0.1	0.5	1.0	4.0	10
λ_{ZnBr_2}	110	105	98	87	82	65	55	23	7.3
λ_{CdBr_2}	—	92	65.6	40.1	31	18.3	15.4	7.9	—

G. Jäger's values for the eq. conductivity of zinc bromide soln. and O. Grotrian's for cadmium bromide soln. show a rise to a maximum as the conc. increases, and this is followed by a rapid fall in the conductivity. Cadmium bromide in dil. soln. is almost as strongly ionized as cadmium chloride, and the **degree of ionization**

rapidly falls as the conc. increases. H. C. Jones and co-workers found the mol. conductivity μ and the percentage degree of ionization, α , of soln. containing a mol of cadmium bromide in v litres to be :

v	.	.	.	4	8	32	128	512	2048
μ_0°	.	.	.	28.63	37.80	57.78	79.77	101.37	121.23
μ_{65}	.	.	.	96.4	128.5	202.3	286.4	369.1	436.0
α_0°	.	.	.	23.1	30.5	46.7	64.4	81.9	97.9
α_{65}°	.	.	.	22.1	29.5	46.4	65.7	84.6	100.0

A. J. Rabinowitsch measured the anomalous ionization—*i.e.* the decreased eq. conductivity with dilution of zinc and cadmium bromides. W. Hallwachs obtained analogous results, and C. Immerwahr found that the conc. of the ions is very sensitive to additions of potassium bromide. G. Kümmell's values for the **transport numbers** of the anions of zinc bromide vary from 0.584 to 0.607, in soln. with respectively 0.00272 and 0.0103 mol of $\frac{1}{2}\text{ZnBr}_2$ per litre. G. Kümmell also found 0.584 for soln. with 0.010 to 0.0026 mol of $\frac{1}{2}\text{CdBr}_2$ per litre. For conc. soln. the evidence, as with the corresponding chlorides, points to the formation of complex anions in conc. soln. V. Gordon found that the transport number of the anions in a conc. soln.—29 per cent.—of CdCl_2 , varies with temp. $\theta=8^\circ$, anion, 0.894; 40° , 1.040; and at 75° , 0.970; the phenomena here are also explained by the formation of complexes. O. Grottrian, F. J. Wershoven, and C. Cattaneo have measured the temp. coeff. of the conductivity of soln. of cadmium bromide; C. J. J. Fox has measured the conductivity of aq. soln. of cadmium bromide sat. with sulphur dioxide. A. Gockel has measured the change in the electromotive force of $\text{Zn} | \text{ZnBr}_2$ and of $\text{Cd} | \text{CdBr}_2$ with variations of temp. According to S. Meyer, the **magnetic susceptibility** of cadmium bromide in powder form referred to mass units is -0.30×10^{-6} .

Soln. of zinc and cadmium bromides are hydrolytically decomposed by water. G. André¹⁴ reported **zinc hexoxydibromide**, $\text{ZnBr}_2.6\text{ZnO}.35\text{H}_2\text{O}$, to be formed by the action of cold water on the tetroxydibromide; **zinc pentoxydibromide**, $\text{ZnBr}_2.5\text{ZnO}.6\text{H}_2\text{O}$, by heating in a sealed tube at 200° a mixture of zinc oxide and bromide; **zinc tetroxydibromide**, $\text{ZnBr}_2.4\text{ZnO}.10\text{H}_2\text{O}$, by heating 100 grms. of zinc bromide with 30 grms. of zinc oxide, and adding a conc. soln. of ammonium bromide until the oxide is dissolved; he also obtained a tridecahydrate, $\text{ZnBr}_2.4\text{ZnO}.13\text{H}_2\text{O}$, by heating a conc. soln. of zinc oxide in zinc bromide, and an enneadecahydrate, $\text{ZnBr}_2.4\text{ZnO}.19\text{H}_2\text{O}$, by adding aq. ammonia to a soln. of zinc bromide in amount insufficient for complete precipitation. G. André has also reported a **zinc diamminotrioxylbromide**, $3\text{ZnO}.\text{ZnBr}_2.2\text{NH}_3.5\text{H}_2\text{O}$, by heating in a sealed tube tridecahydrated zinc tetroxydibromide with water at 200° . A. de Schulten made plate-like crystals of a basic cadmium bromide, or **cadmium oxydibromide**, $\text{CdO}.\text{CdBr}_2.\text{H}_2\text{O}$, that is, $\text{Cd}(\text{OH})\text{Br}$, by heating a soln. of cadmium bromide one or two days with marble in a sealed tube at 200° ; E. Tassilly made the same salt by treating a dil. soln. of cadmium bromide with dil. aqua ammonia. The product has a sp. gr. 4.87 (15°), and heat of soln. 14.35 Cals. It is decomposed by water. Small crystals of the trihydrate, $\text{CdO}.\text{CdBr}_2.3\text{H}_2\text{O}$, were made by E. Tassilly by treating a conc. soln. of cadmium bromide with cadmium oxide in a sealed tube at 200° . The crystals act on polarized light; they are decomposed by water, and more rapidly by alkali lye; and they are readily soluble in acids. A. Mailhe also reported a heptahydrate, $\text{ZnO}.\text{ZnBr}_2.7\text{H}_2\text{O}$, by adding mercuric oxide to an excess of a soln. of zinc bromide.

According to W. Hampe,¹⁵ and J. B. Berthemot, zinc bromide dissolves copiously in anhydrous alcohol; and, according to J. M. Eder, 100 grms. of a sat. soln. of tetrahydrated cadmium bromide in absolute alcohol at 15° contain 20.93 grms. of CdBr_2 . H. Jahn says the sp. gr. of a soln. of 0.27097 or 0.16088 grm. of cadmium bromide in unit vol. of alcohol is 1.0464 or 0.94361 (20°) respectively; and the refractive index of a soln. of sp. gr. 1.0461 (20°) is $\mu_a=1.3950$; $\mu_D=1.3970$; and $\mu_B=1.4027$. H. Jahn found the sp. electromagnetic rotation of the plane of polarization of alcoholic soln. of cadmium bromide of sp. gr. 1.0464 to 0.94361 (20°)

to be on the average 1.3784. C. Helmreich measured the sp. ht., and S. Arrhenius the electrical conductivity and the degree of ionization of alcoholic soln. of cadmium bromide; and C. Cattaneo gives $\mu=14$ as the mol. conductivity at 18° of a 0.001N. soln.

W. Hampe says zinc bromide is soluble in anhydrous ether and the soln. is electrically conducting. J. Nickles prepared an unstable compound of ether with zinc bromide which fumed in air. J. M. Eder says 100 grms. of a sat. soln. of tetrahydrated cadmium bromide in absolute ether contain 0.4 grm. of CdBr_2 at 15° . W. Hampe says zinc bromide is insoluble in carbon disulphide; and E. Beckmann, that it is soluble in quinoline. According to P. Dutoit and E. Aston, the mol. conductivity is $\mu=16.2$ for a soln. of a mol of cadmium bromide in 384 litres of propionitrile. Cadmium bromide, say W. H. Krug and K. P. MacElroy, is soluble in acetone, and, according to A. Naumann, 100 grms. of absolute acetone dissolve 1.559 grms. of cadmium bromide, or 64.5 grms. of acetone dissolve a gram of the salt at 18° —ammonia precipitates $\text{CdBr}_2 \cdot 2\text{NH}_3$; hydrogen sulphide, yellow CdS ; chlorine, CdCl_2 ; etc. According to J. H. Mathews, cadmium bromide is insoluble in allyl mustard oil. Zinc and cadmium bromides also form numerous compounds with phenylhydrazine and other organic bases.

According to A. Potilitzin,¹⁶ oxygen attacks zinc or cadmium bromide at a red heat, forming a mixture of oxide and bromide. According to A. Potilitzin, and M. Berthelot, the bromides are easily reduced when heated in a stream of hydrogen in a glass tube—with cadmium bromide the metal forms an annular deposit with a bright metallic lustre. J. B. Berthelot found zinc bromide to be decomposed by nitric acid, but, according to V. Thomas, it is not attacked by nitrogen peroxide. With mercuric oxide, A. Mailhe obtained zinc oxydibromide, $\text{ZnO} \cdot \text{HgBr}_2 \cdot 8\text{H}_2\text{O}$. H. N. Morse and H. C. Jones obtained a product cadmium subbromide, Cd_4Br_7 , by heating anhydrous cadmium bromide with an excess of metallic cadmium in vacuo, or in an atm. of nitrogen. The remarks with respect to cadmium subchloride are applicable here. M. Herschkowitsch found that the soln. of cadmium in an excess of bromide gave a larger heat of soln. than corresponded with J. Thomsen's data; and M. Wildermann showed that a mol of cadmium bromide, in soln., unites with nearly a mol of bromine, furnishing cadmium tetrabromide, CdBr_4 ; and there is evidence of the formation of the still higher polybromide, CdBr_6 . M. Berthelot prepared a crystalline cadmium hydrobromide, $\text{CdBr}_2 \cdot 2\text{HBr} \cdot 7\text{H}_2\text{O}$, analogous to the corresponding chlorine compound. E. Cornec and G. Urbain also found evidence of the existence of $\text{CdBr}_2 \cdot 2\text{HBr} \cdot n\text{H}_2\text{O}$ on their f.p. curves of soln. of the mixed components. M. Adams found that cadmium bromide unites with hydroxylamine, to form a white crystalline precipitate of cadmium hydroxylamino-bromide, $\text{CdBr}_2(\text{NH}_2\text{OH})_2$, when an alcoholic soln. of cadmium bromide is treated with free hydroxylamine. The salt is readily soluble in hot water, and the soln. quickly deposits a basic salt; it is readily soluble in dil. acids; and insoluble in alcohol and ether. H. Franzen and O. von Mayer prepared compounds of zinc and cadmium bromides with hydrazine, namely, zinc hydrazine-bromide, $\text{ZnBr}_2 \cdot 2\text{N}_2\text{H}_4$, and cadmium hydrazinebromide, $\text{CdBr}_2 \cdot 2\text{N}_2\text{H}_4$.

According to G. Gore,¹⁷ and F. C. Franklin and C. A. Kraus, zinc bromide is very slightly soluble and cadmium bromide is insoluble in liquid ammonia. C. F. Rammeisberg made octahedral crystals of zinc diammino-bromide, $\text{ZnBr}_2 \cdot 2\text{NH}_3$, by saturating a conc. aq. soln. of zinc bromide with ammonia, and concentrating by evaporation. The crystals melt when heated and lose their ammonia; they are decomposed by water into zinc oxide and a soln. of ammonium bromide free from zinc. G. André says the crystals have one mol of water of crystallization. F. Ephraïm also prepared this salt. G. André claims to have prepared $3\text{ZnBr}_2 \cdot 6\text{NH}_3 \cdot \text{H}_2\text{O}$ by cooling a soln. of zinc hydroxide in a boiling 33 per cent. soln. of ammonium bromide. Crystals can be obtained by heating the product with water in a sealed tube at 200° . He also claims to have made $3\text{ZnBr}_2 \cdot 8\text{NH}_3 \cdot 2\text{H}_2\text{O}$ by evaporating a soln. of zinc bromide in cold ammonia; and also $3\text{ZnBr}_2 \cdot 10\text{NH}_3 \cdot \text{H}_2\text{O}$ by concentrating the soln. obtained by leading ammonia gas through a soln. of zinc bromide until the precipitate first formed re-dissolves. There is nothing to show

which of these products are compounds and which mixtures—all are decomposed by water.

C. F. Rammelsberg made **cadmium diammino-bromide**, $\text{CdBr}_2 \cdot 2\text{NH}_3$, by a process analogous to that employed for the zinc salt. H. Croft also made octahedral crystals of this salt by cooling an ammoniacal soln. of zinc bromide; and by adding ammonia to an acetone soln. of zinc bromide; H. Grossmann made it by boiling a supersat. soln. of cadmium hydroxide in a conc. soln. of ammonium bromide; and E. Tassilly found this salt is present in the mother liquid remaining after the preparation of zinc oxybromide by his process. E. Tassilly says the heat of formation is $\text{CdBr}_2 + 2\text{NH}_3 = 35.2$ Cals. E. Tassilly also made crystals of **cadmium triammino-bromide**, $\text{CdBr}_2 \cdot 3\text{NH}_3$, by passing a stream of ammonia gas into an ammoniacal soln. of cadmium bromide; and C. F. Rammelsberg obtained a voluminous white powder of **cadmium tetrammino-bromide**, $\text{CdBr}_2 \cdot 4\text{NH}_3$, by exposing dry cadmium bromide to ammonia gas. H. Croft says that under these conditions 4 to 6 mols of ammonia are taken up by one mol of cadmium bromide. The salt loses its ammonia when heated, and decomposes in water. F. Ephraim found the decomposition temp. of **zinc tetrammino-bromide** to be 143° , and of **zinc hexammino-bromide**, 62° . He also prepared **cadmium hexammino-bromide**, $[\text{Cd}(\text{NH}_3)_6]\text{Br}_2$. **Zinc pentammino-bromide** was made by G. André by leading ammonia into a soln. of zinc bromide in well-cooled aqua ammonia and warming the mixture until the precipitate re-dissolved. When re-cooled, crystals of this salt were obtained which decomposed in air giving off ammonia gas. This was possibly the incompletely ammoniated hexammina-salt.

F. Ephraim¹⁸ prepared a hydrated **ammonium zinc tribromide**, $\text{NH}_4\text{Br} \cdot \text{ZnBr}_2 \cdot \text{H}_2\text{O}$, by evaporating a soln. of the two components in the mol. proportion 1 : 1, until crystallization begins. On cooling small glistening plates separate. When dried on a porous tile, and kept 12 hrs. over calcium chloride, analyses correspond approximately with $\text{NH}_4\text{Br} \cdot \text{ZnBr}_2 \cdot 3\text{H}_2\text{O}$, but there is a doubt if the crystals were adequately dried. C. F. Rammelsberg made deliquescent crystals of $2\text{NH}_4\text{Br} \cdot \text{ZnBr}_2$, or $2\text{NH}_4\text{Br} \cdot \text{ZnBr}_2 \cdot \text{H}_2\text{O}$, by evaporating a soln. of the component salts over sulphuric acid. According to C. H. D. Bödeker, the sp. gr. is 2.625. H. C. Jones and N. Knight, and F. Ephraim report the formation of monoclinic crystals of $3\text{NH}_4\text{Br} \cdot \text{ZnBr}_2 \cdot \text{H}_2\text{O}$ by evaporating a soln. of zinc bromide with equi-molar proportions of ammonium bromide. H. L. Maxwell studied the dissociation of the salt in aq. soln. by the diffusion process.

J. M. Eder¹⁹ obtained crystals of **ammonium cadmium tribromide**, $\text{NH}_4\text{Br} \cdot \text{CdBr}_2$, from a soln. of the component salts; and E. Tassilly, and H. Grossmann by the action of cadmium oxide on ammonium bromide. E. Rimbach says the crystals are anhydrous; and J. M. Eder, that they are not decomposed by water between 0° and 110° ; and that one part of the salt dissolves in 0.73 part of water at 15° ; in 5.3 parts of alcohol of sp. gr. 0.794; in 280 parts of ether, sp. gr. 0.729; and in 24 parts of ethereal alcohol. E. Rimbach and A. Grewe gave the solubility at 1° as 53.82 per cent.; at 14.8° , 58.01 per cent.; at 52.2° , 65.32 per cent.; and at 110.1° , 75.83 per cent., or, the solubility S at θ° between 1° and 110° is $S = 54.47 + 0.197\theta$. K. von Hauer obtained crystals of $\text{CdBr}_2 \cdot 4\text{NH}_4\text{Br}$, from the mother liquid remaining after the separation of $\text{NH}_4\text{Br} \cdot \text{ZnBr}_2$; E. Tassilly, and H. Grossmann by boiling cadmium hydroxide or carbonate with a soln. of ammonium bromide; and E. Rimbach, by crystallization from a soln. containing 6.85 per cent. NH_4 , 14.94 Cd, and 51.48 of bromine. E. Rimbach says that the crystals are trigonal and feebly double refracting with the axial ratio $a : c = 1 : 0.6269$. J. M. Eder says that one part of the salt dissolves in 1.4 parts of water at 15° , and that the salt is decomposed by alcohol and ether. According to E. Rimbach, however, the salt is decomposed by cold water, but not if the temp. be 160° , under which condition the salt may be crystallized.

F. Ephraim²⁰ obtained hygroscopic crystals of **sodium zinc tribromide**, $\text{NaBr} \cdot \text{ZnBr}_2 \cdot \text{H}_2\text{O}$, and of $2\text{NaBr} \cdot \text{ZnBr}_2 \cdot 5\text{H}_2\text{O}$, by the conc. of a soln. with the mol.

proportions in the former case of $\text{NaBr} : \text{ZnBr} = 3 : 4$, and the latter case $2 : 1$. When heated they are decomposed. H. Croft, and J. M. Eder reported the formation of the complex salts, and J. M. Eder says one part of the salt dissolves in 1.04 parts of water at 15° ; in 3.7 parts of alcohol of specific gravity 0.794; and in 190 parts of ether of sp. gr. 0.729. H. C. Jones and N. Knight say $2\text{NaBr}_2 \cdot 3\text{CdBr}_2 \cdot 6\text{H}_2\text{O}$ exists in conc. soln., and is decomposed by dilution; they determined the electrical conductivity of the soln., but they could not make J. M. Eder's salt, $4\text{NaBr} \cdot \text{CdCl}_2$. F. Ephraim prepared **potassium zinc tribromide**, $\text{KBr} \cdot \text{ZnBr}_2 \cdot 2\text{H}_2\text{O}$ and $2\text{KBr} \cdot \text{ZnBr}_2 \cdot 2\text{H}_2\text{O}$, from soln. with the mol. proportions $\text{KBr} : \text{ZnBr}_2 = 1 : 1$ in the former case, and $2 : 1$ in the latter. The crystals of the former are hygroscopic, the latter not so. E. Cornec and G. Urbain measured the lowering of the f.p. of mixed soln. of alkali and cadmium bromides and obtained results in harmony with the composition of the known double salts, $\text{CdBr}_2 \cdot 2\text{MBr}$, where M represents NH_4 , K, Na, or H. H. L. Maxwell studied the dissociation of **sodium cadmium bromide** in aq. soln. by the diffusion process. K. von Hauer made crystals of **potassium cadmium tribromide**, $\text{KBr} \cdot \text{CdBr}_2 \cdot \text{H}_2\text{O}$, by evaporating a soln. of equimolecular proportions of the component salts; the mother liquid gave crystals of $4\text{KBr} \cdot \text{CdBr}_2$. The former crystals are rhombic, the latter are isomorphous with the rhombohedral crystals of the chlorine compound. The axial ratios of the former are $a : b : c = 0.4592 : 1 : ?$; the crystals are stable in air, and, according to H. Croft, very soluble in water; according to J. M. Eder, one part of the salt at 15° dissolves in 0.79 part of water; according to E. Rimbach, water at 0.4° , 15.8° , 50° , and 112.5° dissolves respectively 53.75, 58.68, 68.25, and 78.11 per cent. of the salt, or the solubility S at θ° between 0.4° and 112.5° is $S = 55.108 + 0.218\theta$. $\text{KBr} \cdot \text{NH}_4\text{Br} \cdot \text{H}_2\text{O}$. It is not decomposed by water between 0.4° and 112.5° , but is decomposed by alcohol or ether. H. C. Jones and N. Knight, and C. Immerwahr have measured the electrical conductivity of soln. of $\text{KBr} \cdot \text{CdBr}_2 \cdot \text{H}_2\text{O}$. According to J. M. Eder, the salt $4\text{KBr} \cdot \text{CdBr}_2$ is very deliquescent, and dissolves in 1.4 parts of water at 15° , but, according to E. Rimbach, it is decomposed by water into potassium and cadmium bromides. The effect of the presence of hydrochloric acid, lithium potassium, and calcium chlorides is to hinder the decomposition of the salt by water at 16° . R. G. van Name and W. G. Brown obtained evidence of the formation of potassium cadmium tetrabromide, $2\text{KBr} \cdot \text{CdBr}_2$, in their study of the equilibrium of soln. of the component salts. E. Rimbach prepared **rubidium cadmium tri- and hexa-bromides**, $\text{RbBr} \cdot \text{CdBr}_2$ and $4\text{RbBr} \cdot \text{CdBr}_2$, by evaporating a soln. of the component salts. The solubility S of the former salt at θ° between 0° and 107° is $S = 35.34 + 0.393\theta$, and of the latter between 0° and 115° , $S = 50.88 + 0.2637\theta$. H. L. Wells and G. F. Campbell prepared the **cæsium zinc penta- and tetra-bromides**, $3\text{CsBr} \cdot \text{ZnBr}_2$ and $2\text{CsBr} \cdot \text{ZnBr}_2$, by a process analogous with that employed for the corresponding chlorides; and H. L. Wells and P. T. Walden prepared **cæsium cadmium penta-, tetra-, and tri-bromides**, $3\text{CsBr} \cdot \text{CdBr}_2$; $2\text{CsBr} \cdot \text{CdBr}_2$; and $\text{CsBr} \cdot \text{CdBr}_2$. The two latter are analogous with the corresponding chlorides, but the chloride eq. to $3\text{CsBr} \cdot \text{CdBr}_2$ has not been made. Cs_3CdBr_5 is obtained in rectangular plates from 120 c.c. of a soln. with 80 grms. cæsium bromide and 4.5 grms. of cadmium bromide; and Cs_2CdBr_4 , in slender needles from 120 c.c. of a soln. containing 52 grms. of cæsium bromide and 3 grms. of cadmium bromide. Both salts on recrystallization from water furnish CsCdBr_3 , which is also formed from soln. of the component salts mixed in widely varying proportions. The compound $\text{CsBr} \cdot \text{CdBr}_2$ is dimorphous—cubic when the cæsium bromide is in excess, and in prisms when the cadmium bromide is in excess.

G. Hermann found mixtures of cadmium and cuprous bromides form solid soln. up to 66 per cent. CdBr_2 , at which there is a eutectic at 420° . Cuprous bromide undergoes a transformation at 394° , and **cuprous cadmium tribromide**, $\text{CuBr} \cdot \text{CdBr}_2$, is formed in the solid state. K. von Hauer reported the formation of large colourless crystals of **barium cadmium tetrabromide**, $\text{BaBr}_2 \cdot \text{CdBr}_2 \cdot \text{H}_2\text{O}$, isomorphous with the corresponding chloride, by the spontaneous evaporation of soln. of equal

mol. proportions of the two salts. The existence of the double salt in conc. soln. was confirmed by H. C. Jones and N. Knight, who give the formula $\text{BaBr}_2 \cdot \text{CdBr}_2 \cdot 4\text{H}_2\text{O}$ for the crystals obtained when the cadmium bromide is in excess. H. C. Jones and N. Knight measured the conductivity. The crystals are double refracting, and, according to A. Murmann and L. Rotter, isomorphous with the corresponding chloride. The sp. gr. is 3.665, according to F. W. Clarke, and 3.687, according to H. Topsøe.

§ 14. Zinc and Cadmium Iodides

According to C. Mentzei,¹ iodine occurs in the cadmiferous zinc ores of Silesia, and hence it has been inferred, without proof, that zinc iodide occurs in nature. According to J. L. Gay Lussac, iodine unites readily with zinc with the development of a small proportion of heat, forming a readily fusible mass which when heated sublimes, forming four-sided needle-like crystals. The aq. soln. of zinc iodide was made by J. B. Berthémot by bringing together zinc, iodine, and water until the soln. is decolorized. F. Bodroux illustrated the reaction as a lecture experiment by dropping water on a mixture of zinc dust and iodine. The reaction is quite violent. Zinc iodide is also made by dissolving zinc or zinc oxide in hydriodic acid. The evaporation of the aq. soln. over 0° furnishes octahedral crystals of the

anhydrous salt. A. Stromeyer made cadmium iodide either by the action of iodine on heated cadmium, or the mutual action of iodine, cadmium, and water; F. W. Clarke and E. A. Kebler heated eq. quantities of iodine and cadmium in a sealed tube exhausted of air; and A. Vogel made it by evaporating to dryness a soln. of 20 parts of potassium iodide, and 15 parts of cadmium sulphate. The mass was extracted with absolute alcohol, and the alcoholic soln. of cadmium iodide was allowed to crystallize. C. D. Ragland also made this salt by dissolving cadmium or cadmium oxide in hydriodic acid.

According to J. B. Berthelot,² and C. F. Rammelsberg, anhydrous zinc iodide forms octahedral crystals belonging to the cubic system; measurements of the crystals of cadmium iodide by J. Grailich, and A. E. Nordenskjöld show that they belong to the hexagonal system and have the axial ratio $a:c=1:0.8599$; but R. M. Bozorth's **X-radiograms** correspond with a trigonal not hexagonal structure. The shortest distance between the centres of the iodine and cadmium atoms is 3.00 Å.; and between the iodine atoms, 4.21 Å. A. G. Duboin prepared mixed crystals of mercuric iodide with cadmium and zinc iodides, without determining their form. A. des Cloizeaux also showed the crystals have a strong negative double refraction. According to J. W. Retgers, cadmium iodide is closely related crystallographically with lead iodide. E. Cohen and A. L. T. Mösveld examined the crystallization of supersat. aq. soln. of cadmium iodide and found that the velocity may be slow owing to the presence of a third substance—possibly cadmium hydroxide, a product of hydrolysis. W. Ackroyd drew attention to the change in colour of the warm iodides with increasing mol. wt. in passing along the series: Magnesium iodide (white), zinc iodide (white), cadmium iodide (white), and mercuric iodide (red). H. C. Jones and C. G. Carroll say that when heated for a long time on an air-bath, cadmium iodide acquires a red colour, which on introducing a trace of water becomes reddish-white. W. Hampe also states that molten cadmium iodide is dark brown; the colour becomes paler on solidification, and on cooling becomes white. W. Hampe says melted zinc iodide is yellow.

The **specific gravity** of anhydrous zinc iodide, according to C. H. D. Bödeker,³ is 4.696 at 10° and 4.666 at 14.2°; F. W. Clarke and E. A. Kebler gave 4.666. The sp. gr. of the so-called α -variety of cadmium iodide by F. W. Clarke vary from 5.543 to 5.729 (10.5° to 20°); H. B. Fullerton gives 5.9857 (12°) and 5.9738 (13.5°), and for the β -variety 4.596 to 4.688. C. H. D. Bödeker gives 4.596 (10°); F. W. Clarke and E. A. Kebler, 5.644; and J. F. Snell, 5.644. If cadmium iodide be crystallized from its soln. in hydriodic acid the product has a lower sp. gr. than normal cadmium iodide. The marked difference in the sp. gr. has led F. W. Clarke to the assumption that there are two allotropic forms called respectively α - and β -varieties. The normal or α -salt with the higher sp. gr. is white, and is unchanged by heating it to 250°; the less stable β -salt with the lower sp. gr. is brownish, loses weight at 40°, and on losing weight acquires a higher sp. gr. The conditions of preparation of the less stable salt are not clear. F. W. Clarke made it by the action of hydriodic acid on cadmium and on cadmium carbonate; but F. W. Short believed that the so-called β -form is an impure variety of the α -form in that the α -form with air bubbles gives the β -variety, and J. F. Snell said that the low sp. gr. form behaves like a mixture of cadmium iodide, hydrogen iodide, and water. E. Cohen and A. L. T. Mösveld confirm the existence of α - and β -CdI₂, and say that whether prepared by crystallization from soln. or by the condensation of its vapour, ordinary cadmium iodide is a mixture of these two forms, and therefore the properties usually ascribed to cadmium iodide are really the properties of a mixture.

E. Cohen and co-workers represent the **specific volume**, v , of soln. containing c grms. of CdI₂ per gram of soln. by $v=1.00435-0.820924c+0.016857c^2$. W. Biltz gave 64.88 for the mol. vol. of cadmium iodide. According to S. Motylowsky, the drop weights W of molten zinc and cadmium iodides at their m.p. are respectively 46 and 58, when the **surface tension** σ is $\sigma=0.076W$. C. A. Valson gives 50.6, 58.0,

55.8, . . . and 50.5, as the relative capillary heights h in a $\frac{1}{2}$ mm. tube of soln. of cadmium iodide containing respectively 0, 5, 10, . . . and 25 grms. of CdI_2 per 100 c.c. of water at 15° ; similarly, he obtained $h=58.0, 55.8, . . .$ and 50.5 for soln. with 5, 10, . . . and 25 grms. of cadmium iodide in 100 grms. of water. A soln. with a grm. eq. of cadmium iodide has $h=52.3$, and the sp. gr. of the soln. is 1.142, at 15° , hence, Dh , the surface tension, is 60.7, a greater value than for water alone.

The **melting point** of zinc iodide is $446^\circ \pm 1^\circ$, according to T. Carnelley;⁴ 446° , according to W. Hampe; and 450° , according to L. Graetz. For cadmium iodide, O. Ruff and W. Plato give 350° ; H. Brand, 385° ; G. Hermann, 392.4° ; and W. Hampe, and L. Graetz, 404° . According to R. Nacken, the f.p. in the cooling curve appears at 385° , and he could detect no signs of allotropic modifications in the heating or cooling curves. O. Ruff and W. Plato obtained a rounded curve with mixtures of cadmium fluoride and iodide with cadmium iodide, Fig. 43. The

FIG. 43.—Fusion point Curves of Binary Mixtures of Cadmium Iodide with Cadmium Fluoride, Chloride, and Bromide.

latter has a minimum at about 348° and 90 molar per cent. of the iodide. R. Nacken also found the f.p. of cadmium bromide (567°) with increasing proportions of cadmium iodide falls steadily to the value for cadmium iodide, Fig. 42; mixtures with cadmium chloride give the typical V-eutectic at 360° with 70 molar per cent. of cadmium iodide, Fig. 42.

According to the vap. density determinations of A. Scott,⁵ cadmium iodide is partially dissociated. According to E. Beckmann, the **molecular weight** of zinc iodide in boiling quinoline is 320—the calculated value for ZnI_2 is 319.1; and for cadmium iodide, 363—the calculated value for CdI_2 is 364.72. Hence the mol. wts. are here nearly normal. For cadmium iodide in boiling water, S. M. Johnston, E. Beckmann, and W. Landsberger find a mol. wt. 333 to 366; E. Beckmann found in alcohol 313 to 361; H. C. Jones found in acetone 448.6 to 510.7; S. Schröder and H. Steiner found in methyl acetate 176.8 to 183.3; and A. Werner found in piperidine, 365.21; in pyridine, 348.34; in methyl sulphide, 356; and in ethyl sulphide, 369. G. Tammann found the lowering of the vap. press. of aq. soln. corresponded with an abnormal mol. wt.

According to H. Fizeau,⁶ the coeff. of **linear expansion** of crystals of cadmium iodide is 0.000029161 at 40° ; and the coeff. of expansion of the molten salt is positive and relatively large. P. Kremers has measured the **volume expansion** of soln. of zinc iodide at different temp.—vol. at 19.5° unity. With 18.8 mols of ZnI_2 in 100 parts of water, the volume at 0° is 0.99403; at 40° , 1.00877; at 60° , 1.01960; at 80° , 1.03249; and at 100° , 1.04751; similarly with soln. with 198.4 mols of ZnI_2 , 0.98736 at 0° ; 1.01392 at 40° ; 1.02815 at 60° ; 1.02815 at 80° ; 1.04269 at 100° ; and 1.05756 at 100° . For cadmium iodide with 22.6 mols. per 100 grms. of water, 1.00863 at 40° ; 1.01935 at 60° ; 1.03218 at 80° ; 1.04667 at 100° ; and with 46.4 mols of CdI_2 , 1.01027 at 40° ; 1.02198 at 60° ; 1.03523 at 80° ; and 1.04995 at 100° . In both cases the coeff. of expansion increases with increasing conc.

C. Helmreich gives the **specific heat** of cadmium iodide as 0.05264 between 0°

and 30°; 0.05274 between 0° and 50°; and 0.05277 between 0° and 70°. W. Timofeff said that the sp. ht. of conc. aq. soln. of cadmium iodide is but one-third the value for alcoholic soln.; for dil. soln., the sp. ht. is nearly the same as the solid; C. Helmreich found for 15.16, 29.99, and 45.70 per cent. soln. the respective sp. ht. 0.87235, 0.72725, and 0.57953 between 0° and 30°; and 0.83952, 0.70932, and 0.56936 between 0° and 70°.

J. Thomsen's ⁷ value for the **heat of formation** of zinc iodide from its elements (Zn, I_2) = 49.23 Cals., and for cadmium iodide (Cd, I_2), 48.83 Cals. T. J. Webb obtained 49.9 Cals. for the heat of formation of zinc iodide; and H. S. Taylor and G. S. J. Perrott gave 48.5 Cals. for the heat of formation of cadmium iodide from its elements. According to R. de Forcrand, the heat of formation of zinc iodide in aq. soln. is 61.23 Cals. J. Thomsen also gives for the **heat of solution** of a mol. of zinc iodide in 400 mols. of water at 18°, 11.31 Cals., and likewise for cadmium iodide, -0.96 Cal.

The **solubility** of zinc iodide in water has been determined by E. Lubarsky,⁸ F. Mylius and R. Dietz, and A. Étard:

Per cent. ZnI_2	-5°	0°	18°	40°	60°	80°	100°
	80.77	81.11	81.20	81.66	82.37	83.05	83.62
Solid phase	$\text{ZnI}_2 \cdot 2\text{H}_2\text{O}$			ZnI_2			

Below -7°, tetrahydrated zinc iodide, $\text{ZnI}_2 \cdot 4\text{H}_2\text{O}$, is the stable form in aq. soln., and the transition point is -7° when dihydrated zinc iodide, $\text{ZnI}_2 \cdot 2\text{H}_2\text{O}$, appears, and it is transformed into the anhydrous salt at 0°. The solubility curve of $\text{ZnI}_2 \cdot 2\text{H}_2\text{O}$ has been extended by R. Dietz into the metastable region 10°, 82.06; 22°, 83.12; and 27°, 89.52 per cent. A. Étard gives the solubility at 140° as 83.6 per cent. J. B. Berthemot prepared **dihydrated zinc iodide**, $\text{ZnI}_2 \cdot 2\text{H}_2\text{O}$, in 1828; and R. Dietz found that this salt separates in prismatic deliquescent crystals when a 83.5 per cent. soln. of neutral zinc iodide is cooled to -8°; at 27° the crystals partially fuse and become anhydrous. According to E. Lubarsky, **tetrahydrated zinc iodide**, $\text{ZnI}_2 \cdot 4\text{H}_2\text{O}$, crystallizes from a sat. soln. when a crystal of $\text{ZnCl}_2 \cdot 3\text{H}_2\text{O}$ is added; it melts at -7° with the formation of the dihydrated salt. It is not definitely settled whether the alleged tetrahydrated salt is not a trihydrated salt.

The solubility of cadmium iodide in water has been measured by P. Kremers,⁹ A. Stromeyer, J. M. Eder, A. Étard, and R. Dietz:

Per cent. CdI_2	-7.5°	0°	18°	40°	50°	75°	100°
	43.5	44.4	46.0	48.4	49.35	52.65	56.08

Ice is the solid phase below the eutectic temp. -7.5°, and at -3.4° the solubility curve has 33.3 per cent. CdI_2 , and at -2.2°, 26.5 per cent. A. Étard gives the solubilities 63.1, 70.7, and 81.5 per cent. CdI_2 respectively at 140°, 185°, and 255°. E. Cohen and co-workers represented the solubility S in grms. of cadmium iodide in 100 grms. of soln. by $S = 46.793 + 0.1003(\theta - 30) + 0.0003256(\theta - 30)^2$; the *temperature coefficient*, $dS/dT = +0.1003 \pm 0.001$ grm. per 100 grms. of soln. per degree; and the *pressure coefficient*, $dS/dp = 0.00390 \pm 0.0002$ per cent. per atm. at 30°. No definite hydrated salts have been demonstrated.

The **specific gravities** of aq. soln. of zinc iodide by P. Kremers¹⁰ are for soln. with w grms. per 100 grms. of water at 19.5°:

w grms. ZnI_2	21.5	46.4	85.0	126.3	177.9	232.0
Sp. gr.	1.1715	1.3486	1.5780	1.7815	1.9906	2.1853

P. Kremers, C. A. Valson, O. Grotrian, F. J. Wershoven, and many others have determined the sp. gr. of soln. of cadmium iodide. From O. Grotrian's and F. J. Wershoven's values at 18°:

Per cent. CdI_2	0.0429	0.399	1.017	4.87	10.03	19.54	29.60	44.13
Sp. gr.	0.99908	1.0021	1.0073	1.0413	1.0885	1.1890	1.3171	1.5573

A. J. Rabinowitsch measured the sp. gr. and **viscosity** of soln. of zinc and cadmium iodides.

The **lowering of the vapour pressures** of aq. soln. of cadmium iodide have been measured by J. Moser,¹¹ and G. Tammann; the latter found for soln. with 29.35, 59.56, and 113.22 grms. of CdI_2 in 100 grms. of water the respective lowerings 12.4, 26.4, and 55.9 mm. J. Moser found a minimum in the relative lowering of the vap. press. E. Beckmann, F. Jüttner, W. Landsberger have investigated the **raising of the boiling points** of aq. soln. of cadmium iodide. The value of J. H. van't Hoff's boiling constant varies from 1.00 to 1.05 as the conc. of the soln. rises from 0.119 to 0.651 mol of cadmium iodide per litre. F. Rüdorff, S. Arrhenius, H. C. Jones, V. J. Chambers and C. W. Frazer, and J. W. McBain have investigated the **lowering of the freezing points** of aq. soln. of cadmium iodide. The value of J. H. van't Hoff's freezing constant i falls from 2.40 to 1.24 when the conc. rises from 0.00105 to 0.1001 mol of cadmium iodide per litre.

A. des Cloizeaux¹² found the crystals of cadmium iodide have a strongly negative double refraction. J. A. Wilkinson says the fluorescence of cadmium iodide is white, the phosphorescence is feeble, and the thermoluminescence strong. P. Kremers found the **refractive indices** of soln. of zinc iodide of sp. gr. 1.4033, 1.5563, and 2.0286 at 19.5° to be respectively 1.4049, 1.4308, and 1.5090 at 15°. Similarly, for soln. of cadmium iodide of sp. gr. 1.2934 and 1.5983 at 19.5°, the refractive indices are 1.3792 and 1.4293 at 16°. C. Bender, H. Jahn, R. de Muyneck, F. H. Getman and F. B. Wilson, and M. le Blanc and P. Rohland have also measured the refractive indices of soln. of cadmium iodide. According to H. Jahn, at 20°, soln. of sp. gr. 1.1541 and 1.5181 have respectively $\mu_a=1.3556$ and 1.4142; $\mu_D=1.3580$ and 1.4176; and $\mu_B=1.3634$ and 1.4163. P. Barbier and L. Roux have measured the **dispersion** of soln. of cadmium iodide; and H. Jahn found the specific **electromagnetic rotation** of the plane of polarization with soln. of sp. gr. 1.1541 to 1.5181 (20°) to be nearly 2.0133, and J. Forchheimer also found the mol. magnetic rotation to be independent of the conc. or degree of ionization of the soln. C. Sheard and C. S. Morris measured the **emission spectrum** of zinc iodide and found bands between 5610 and 5535; 5195 and 5116; and between 4829 and 4780. They found some emission spectral bands with cadmium iodide, but rapid vaporization prevented accurate measurements. E. J. Evans studied the **absorption spectrum** of cadmium iodide vapour.

F. Braun¹³ says that solid anhydrous zinc iodide does not conduct electricity electrolytically; M. Faraday and W. Hampe have shown that the molten iodide is a good conductor; W. Hampe makes a similar remark about cadmium iodide. L. Graetz found the **electrical conductivity**, $K \times 10^8$, in Siemens' units (mercury unity) is:

	520°	500°	480°	460°	450°	440°	420°	410°
$K \times 10^8$	1660	1500	1325	1140	1050	630	300	30

and likewise for cadmium iodide:

	440°	420°	410°	404°	400°	380°	320°	270°
$K \times 10^8$	3470	2780	2600	2490	2440	2175	750	2.5

There is a break in the resulting curve in passing from the solid to the liquid state. According to G. C. Schmidt and W. Hechler, the vap. of zinc iodide is an electrical conductor, and A. E. Garrett and R. S. Willows have shown that when the iodide is heated, it ionizes the surrounding gas.

G. Jäger gives for the eq. conductivity of soln. with 0.025, 0.0125, 0.00625, and 0.003125 gram-eq. of zinc iodide per litre at 22°, 103.08, 105.12, 110.56, and 115.52, respectively; and S. M. Johnston, for the eq. conductivity of soln. with 0.312, 1, 10, 1000 mols of cadmium iodide per litre, 269, 406, 984, and 3317 respectively. H. C. Jones and co-workers found the mol. conductivity, μ , and the percentage degree of ionization, α , of soln. with a mol of cadmium iodide in v litres, to be

v	4	8	32	128	512	2024
μ_{30}°	20.45	24.31	39.45	62.73	87.06	109.01
μ_{65}°	74.96	94.61	161.3	254.8	345.5	414.5
α_0°	17.2	20.5	33.2	52.8	73.3	91.7
α_{65}°	18.5	22.8	38.9	61.4	83.3	100.0

A. J. Rabinowitsch measured the anomalous ionization—*i.e.* the decrease in the eq. conductivity with dilution—of soln. of zinc and cadmium iodides. According to J. W. McBain, cadmium iodide is almost completely converted into a complex salt in conc. soln., and consequently, the calculations of α are uncertain because of the formation of complexes. H. C. Jones' observations show that under similar conditions, cadmium iodide ionizes less rapidly than the bromide, and the latter, in turn, less readily than the chloride. The **transport numbers** for the anions with zinc iodide in 0.976*N*-, 0.488*N*-, and 0.248*N*-soln. are respectively 0.602, 0.586, and 0.579; and H. Jahn found that for soln. with a mol of zinc iodide in 4.02 and 300.4 litres, the transport number falls from 1.003 to 0.558. From the data for the conductivities, lowering of the f.p., and the transport numbers, J. W. McBain calculates that in a $\frac{1}{10}$ *N*-soln. of cadmium iodide, about 80 per cent. of non-ionized iodide is present, and about half the anions are CdI_3' and half CdI_4'' . Data for the transport numbers of cadmium iodide have also been given by W. Hittorf, G. Heym, R. Lenz, W. Bein, V. Gordon, G. Carrara, H. Jahn, etc.; and for zinc iodide by W. Hittorf, and G. Kümmell.

A. P. Laurie¹⁴ has investigated the **electrical potential** of the combinations $\text{Zn} | \text{ZnI}_{2\text{soln.}}, \text{I}_2 | \text{Pt}$ at 20° and with 0.309 to 0.0006 grm. of iodine per c.c. of soln. of 0.33 grm. of ZnI_2 per gram of water the potential changes only from 1.287 to 1.221 volts; and with 0 to 3.87 grms. of zinc iodide per gram of a solution with 0.14 grm. of iodine per c.c. from 1.594 to 1.075 volts. In the combination $\text{Zn} | \text{ZnI}_{2\text{soln.}}, \text{CuI} | \text{Cu}$, with 0 to 3.9 grms. of ZnI_2 per gram of water, the potential falls from 0.894 to 0.415 volt. Similarly, for the combination $\text{Cd} | \text{CdI}_{2\text{soln.}}, \text{I}_2 | \text{Pt}$, the potential falls from 1.087 to 1.039 volts, when the number of grains of iodine per c.c. of a one per cent. soln. of cadmium iodide changed from 0.0032 to 0.00005. T. J. Webb found that the e.m.f. of the cell $\text{Ag} | \text{Ag} | \text{ZnI}_2 \text{ (sat. soln.)} | \text{Zn}$ (amalgam) to be 0.39872 volt at 25°, and the temp. coeff. -0.000094 . A. Hagenbach found for a temp. difference of 70°, the e.m.f. of the combinations $\text{Cd} | \text{CdI}_2$ and $\text{CdI}_2 | \text{Cd}$ with soln. with a mol of cadmium iodide per 10 and 100,000 litres fell from 0.0623 to 0.0522 volt. E. Cohen and co-workers represented the e.m.f., E , of cadmium in cadmium soln. containing c grms. of the salt per 100 grms. of soln. at 30°, by $E = 0.46338 - 0.0009461c - 0.00000011c^2$. S. Meyer found the **magnetic susceptibility** of powdered cadmium iodide to be -0.25×10^{-6} mass units at 18°.

Zinc and cadmium iodides are among the few metal iodides soluble in alcohol.¹⁵ According to J. M. Eder, at 15°, one part of cadmium iodide is dissolved by 0.98 part of alcohol of sp. gr. 0.794, or the solubility is 50.5 per cent. According to W. Timofejeff, at 20°, 100 grms. of a sat. methyl alcohol soln. contain 59.0 grms. of CdI_2 ; of ethyl alcohol, 42.6 grms.; and of propyl alcohol, 28.9 grms. CdI_2 . The sp. gr. of soln. of cadmium iodide in alcohol have been determined by G. Carrara and M. G. Levi, H. Jahn, C. Cattaneo, and by M. le Blanc and P. Rohland. At 18°, soln. with 0.4290, 0.0108, and 0.0021 mol of cadmium iodide per litre have sp. gr. 0.863, 0.796, and 0.796 respectively. The **molecular volume** of cadmium iodide in alcohol soln. has also been investigated by G. Carrara and M. G. Levi. R. Lenz has investigated the **velocity of diffusion** of cadmium iodide in alcoholic soln.; and W. Herz and M. Lewy, the *partition* of cadmium iodide between water and amyl alcohol, and the results show either that the salt is polymerized in the alcoholic soln. or complex ions are formed. W. Timofejeff, and C. Helmreich have measured the **specific heats** of alcoholic soln. of cadmium iodide. S. Arrhenius has measured the **lowering of the freezing point** of alcoholic soln., and E. Beckmann, W. Landsberger, H. C. Jones the **raising of the boiling point**. The **indices of refraction** of soln. of cadmium iodide in alcohol have been measured by M. le Blanc

and P. Rohland, and likewise by H. Jahn, who has also measured the sp. **electromagnetic rotation** of the plane of polarized light. The **electrical conductivities** and temp. coeff. of soln. of cadmium iodide in various alcohols have been measured by N. Zelinsky and S. Krapivin, H. C. Jones and C. F. Lindsay, W. Hampe, W. Hittorf, C. Cattaneo, R. Lenz, C. Nordmann, etc. According to H. C. Jones and C. G. Carroll, for soln. of a mol of cadmium iodide in *v* litres of 25 and 100 per cent. methyl and ethyl alcohol at 0°, the mol. conductivities are :

<i>v</i>	16	32	64	128	256
25 per cent. CH ₃ OH	33.83	42.10	55.02	70.22	87.31
100 per cent. CH ₃ OH	13.39	14.51	14.83	16.82	20.01
25 per cent. C ₂ H ₅ OH	26.97	34.90	44.21	54.54	69.71
100 per cent. C ₂ H ₅ OH	2.29	2.30	2.32	2.39	2.66

The **transport numbers** of the ions in alcoholic soln. have been measured by W. Hittorf; and A. Campetti, and H. C. Jones find that alcoholic soln. are positive towards aq. soln. The marked tendency of cadmium iodide to polymerize or form complex ions, and its marked solubility in many non-aq. solvents, have attracted many investigators to a study of the behaviour of this salt in non-aq. solvents.

W. Hampe found cadmium iodide is soluble in anhydrous *ether*, and J. M. Eder says that the solubility in absolute ether is 21.7 per cent., and, according to C. E. Linebarger, ethyl ether at 0°, 15°, and 20.3° dissolves respectively 0.03, 0.04, and 0.05 per cent. of cadmium iodide. C. Cattaneo says the sp. conductivity of a soln. of 0.095 gm. of cadmium iodide in 100 grms. of ether referred to mercury at 0° is 0.556×10^{-12} . W. Eidmann says zinc iodide is soluble in *acetone*, and, according to A. Naumann, the sp. gr. of a sat. soln., containing 20 per cent. of cadmium iodide, is 0.994 (18°). P. Dutoit and E. Aston have measured the conductivity and H. C. Jones the b.p. of acetone soln. of *cadmium iodide*. J. Schröder and H. Steiner give the solubility of cadmium iodide in *methyl acetate* as 0.70 to 1.50 per cent., and 2.10 per cent. at the b.p. Cadmium iodide is slightly soluble in *ethylamine*, according to F. L. Shinn, and insoluble in *allyl mustard oil*. C. E. Linebarger gives the solubility of cadmium iodide in *benzene* at 16° and 35° as 0.01 and 0.02 per cent. respectively. G. Coffetti has studied the conductivity of soln. of cadmium iodide in *nitromethane*; P. Dutoit and E. Aston, in *propionitrile*, *methyl ethyl ketone*, and *methyl propyl ketone*; P. Dutoit and L. Friderich, in *acetophenone* and *acetonitrile* soln.; L. Kahlenberg, in *acetonitrile* soln.; L. Kahlenberg and E. O. Ruhoff, *amylamine* soln.; A. Werner and P. Ferchland measured the b.p. of soln. of cadmium iodide in *methyl and ethyl sulphides*, *piperidine*, and *pyridine*; P. Walden and M. Centnerszwer found that cadmium iodide dissolves in liquid *sulphur dioxide* more readily in the presence of alkali iodides than in their absence; M. Centnerszwer noted that the same salt is insoluble in liquid *cyanogen*; P. Walden found that cadmium iodide is almost insoluble in *arsenic tribromide*, and soluble in *sulphur chloride*, S₂Cl₂, and in *sulphuryl chloride*, SO₂Cl₂. E. Beckmann found zinc and cadmium iodides to be soluble in *quinoline*. J. W. Klever said that 100 parts of *glycerol* at room temp. dissolve 40 parts of zinc iodide. W. Hampe said that zinc iodide is insoluble in *carbon disulphide*.

Zinc and cadmium iodides are very deliquescent salts. According to C. F. Rammsberg,¹⁶ conc. aq. soln. of zinc iodide give a gelatinous precipitate of zinc hydroxide on dilution. Aq. soln. are hydrolytically dissociated. A number of basic zinc iodides, or zinc oxyiodides, has been reported. W. Müller said that an oxyiodide is precipitated on cooling the clear hot filtered liquid resulting from the prolonged digestion of zinc with iodine and water; T. Rettie has also reported zinc oxyiodides of uncertain composition to be formed by adding potash-lye in the presence of iodine to a soln. of zinc acetate. E. Tassilly heated a soln. of 20 grms. of zinc iodide, 20 grms. of water, and 0.2 gm. of zinc oxide in a sealed tube for 12 hrs. at 150°, and obtained hexagonal crystals of **zinc enneaoxydiiodide**, 9ZnO.ZnI₂.24H₂O, which are stable in cold water, and lose no water at 120°, but are decomposed at 180°. Fine needle-like crystals of **zinc pentaoxydiiodide**, 5ZnO.ZnI₂.11H₂O, were also obtained by adding dil. ammonia to a soln. of zinc iodides; the crystals are decomposed by water. The oxyiodides, said E. Tassilly, have a smaller heat of formation than the oxybromides, and the latter, in turn, smaller than the oxychlorides; and for 5ZnO.ZnI₂.11H₂O he gave the heat of soln. as 115.5 Cals. E. Tassilly precipitated basic cadmium iodide or **cadmium**

oxydiiodide, $\text{CdO} \cdot \text{CdI}_2 \cdot \text{H}_2\text{O}$, or $\text{Cd}(\text{OH})\text{I}$, by treating a dil. soln. of cadmium iodide (1 : 10) with dil. aqua ammonia—some $\text{CdI}_2 \cdot 2\text{NH}_3$ remains in soln. The crystals act on polarized light; are decomposed by water; and have a heat of soln. of 25·81 Cals. E. Tassilly also made $\text{CdO} \cdot \text{CdI}_2 \cdot 3\text{H}_2\text{O}$ by heating a conc. soln. of cadmium iodide and oxide at 200° in a sealed tube. The crystals are doubly refracting; and are not decomposed in water. G. Carrara found a small quantity of a basic iodide to be formed during the electrolysis of a soln. of cadmium iodide with a cadmium anode, and platinum cathode.

According to J. A. Buchner,¹⁷ zinc iodide decomposes on exposure to moist air in the cold but not in dry air; J. L. Gay Lussac, and M. Berthelot have noted that when heated in air the iodine can be displaced by oxygen, and W. Hampe says that if air be not excluded when the salt is fused some zinc oxide is formed. According to D. J. P. Berridge, if zinc iodide is quite pure, it is not decomposed by light, but it is decomposed if cellulose be present; similar remarks apply to cadmium iodide. M. Berthelot found the iodides are reduced by *hydrogen* at a red heat. Unlike cadmium bromide and chloride, the iodide is oxidized by *nitrogen peroxide* at ordinary temp.: $\text{CdI}_2 + \text{NO}_2 = \text{CdO} + \text{NO} + \text{I}_2 + 66\cdot4$ Cals. C. F. Rammelsberg says zinc iodide is decomposed by *sulphuric acid*, forming sulphur dioxide, iodine, and zinc sulphate. According to C. F. Schönbein, *sulphur dioxide* immediately colours zinc iodide yellow and the colour disappears on warming, or on adding potassium hydroxide or ammonia. According to A. Naumann and co-workers, soln. of cadmium iodide in acetone give a white precipitate of $\text{CdI}_2 \cdot 2\text{NH}_3$ with ammonia; a white precipitate of cadmium sulphide, CdS , with hydrogen sulphide—with very conc. soln., $2\text{CdS} \cdot \text{CdI}_2$, is first precipitated; silver nitrate gives a white precipitate of silver iodide, AgI ; with mercuric chloride, a mixture of cadmium chloride and mercuric iodide; with cupric chloride, a white precipitate of cadmium chloride and cupric iodide, some free iodine being simultaneously formed. An ethyl acetate soln. of cadmium iodide gives with mercuric chloride a white precipitate of cadmium chloride. H. N. Morse and H. C. Jones heated cadmium iodide with an excess of cadmium in vacuo, or in an atm. of nitrogen and obtained a product, $\text{Cd}_{12}\text{I}_{23}$, which is probably not *cadmium subiodide* but a solid soln. of cadmium in cadmium iodide. According to S. Baup, an aq. soln. of zinc iodide takes up as much iodine as it already contains, and the soln. becomes brown. The soln. is supposed to contain **zinc polyiodide**, ZnI_4 , which, according to E. Rimini and F. Olivari, is soluble in fenchone. C. K. Tinkler found that the addition of the iodide of sodium, potassium, barium, magnesium, zinc, aluminium, hydrogen, ammonium, or tetramethylammonium to 0·001N-soln. of iodine in water changed the colour from reddish-brown to yellow, and the soln. gave identical absorption spectra. Hence it was inferred that all these soln. probably contain the same ion, *viz.*, I_3 . R. G. van Name and W. G. Brown also studied the formation of zinc and cadmium polyiodides and polybromides. If **cadmium polyiodide** be CdI_4 the ionization is: $\text{CdI}_4 \rightleftharpoons \text{CdI} + \text{I}_3^-$. C. K. Tinkler says the polyiodide is probably CdI_3 . H. M. Dawson found that cadmium iodide does not dissolve with iodine in nitrobenzene soln. C. W. Blomstrand obtained indications of the formation of an *ammonium zinc periodide*, in violet plates by the action of zinc iodide and a soln. of iodine in ammonium iodide. By passing hydrogen iodide through a mixture of solid cadmium iodide and its sat. soln. at 0° , a dark brown fuming liquid is obtained from which D. Dobroserdoff separated colourless needle-like crystals of **cadmium hydroiodide**, $\text{CdI}_2 \cdot \text{HI} \cdot 3\text{H}_2\text{O}$, on cooling to $-4\cdot7^\circ$. The crystals are stable in the mother liquid, or in an atm. of hydrogen iodide, but not in air. M. Berthelot also obtained crystals of cadmium hydroiodide by cooling to -25° a sat. soln. of cadmium iodide in hydriodic acid. E. Cornec and G. Urbain found that the f.p. of mixed soln. of cadmium iodide and hydriodic acid corresponded with the formation of $\text{CdI}_2 \cdot 2\text{HI} \cdot n\text{H}_2\text{O}$. The compound **zinc iodochloride**, $\text{ZnCl}_2 \cdot 2\text{ICl}_3 \cdot \text{H}_2\text{O}$, has been indicated in connection with zinc chloride. H. Franzen and O. von Maver¹⁸ prepared **zinc hydrazine iodide**, $\text{ZnI}_2 \cdot 2\text{N}_2\text{H}_4$, and **cadmium hydrazine iodide**, $\text{CdI}_2 \cdot 2\text{N}_2\text{H}_4$.

According to G. Gore,¹⁹ and E. C. Franklin and C. A. Kraus, zinc iodide is moderately soluble in liquid ammonia; while, according to G. Gore, cadmium iodide is insoluble, and, according to E. C. Franklin and C. A. Kraus, it is slightly soluble. Note the decreasing solubility of the zinc halides in liquid ammonia in passing from the iodide to the bromide which is slightly soluble, and the chloride and fluoride which are insoluble. C. F. Rammelsberg and E. Tassilly found that zinc iodide absorbs dry ammonia with the development of heat; and the mass swells up, forming a voluminous white powder, probably **zinc hexammino-iodide**, $\text{ZnI}_2 \cdot 6\text{NH}_3$, which is decomposed by water with the separation of zinc hydroxide. Cadmium iodide under similar conditions, said C. F. Rammelsberg, forms **cadmium hexammino-iodide**, $\text{CdI}_2 \cdot 6\text{NH}_3$. Zinc and cadmium hexammino-iodides were studied by F. Ephraim. He gave 65° for the decomposition temp. of the zinc salt. The spontaneous evaporation of a soln. of zinc iodide in aq. ammonia gives white bipyramidal rhombic crystals of **zinc tetrammino-iodide**, $\text{ZnI}_2 \cdot 4\text{NH}_3$, with axial ratios, according to C. F. Rammelsberg, $a : b : c = 0.7922 : 1 : 0.5754$. F. Ephraim found the zinc salt decomposed at 199° . E. Tassilly gives the heat of soln. as 22.35 Cals., but the crystals are decomposed like the hexammino-salt by water. J. MacCrae and H. M. Dawson obtained indications of the possible formation of *cadmium tetramminoiodide*. E. Tassilly reported an ammino-iodide, $3\text{ZnI}_2 \cdot 5\text{NH}_3 \cdot \text{H}_2\text{O}$, as a result of the action of zinc oxide on a soln. of ammonium iodide; this product may not be a chemical individual. F. Ephraim prepared **zinc diammino-iodide**, $\text{Zn}(\text{NH}_3)_2\text{I}_2$. E. Tassilly made octahedral crystals of **cadmium diammino-iodide**, $\text{CdI}_2 \cdot 2\text{NH}_3$, by cooling a hot soln. of cadmium iodide in aqua ammonia, and as a by-product in the preparation of cadmium oxyiodide (*q.v.*). H. Grossmann also made the same compound by the action of conc. aqua ammonia or ammonia gas on cadmium iodide, and by the prolonged boiling of cadmium hydroxide with ammonium iodide. A. Naumann and W. Müller made it by the action of ammonia on an acetone soln. of cadmium iodide. A. Agrestini proposed to utilize the ready formation of these crystals as a reagent for the micro-detection of cadmium. The compound is decomposed by water; E. Tassilly gives the heat of soln. as 11.9 Cals.; and the heat of formation, 29.6 Cals. It melts when heated giving off ammonia and forming cadmium iodide. F. Ephraim and P. Mosimann made some poly-iodides—*e.g.* **zinc tetrammino-hexaiodide**, $[\text{Zn}(\text{NH}_3)_4]_2\text{I}_2 \cdot 2\text{I}_2$; and **cadmium tetrammino-hexaiodide**, $[\text{Cd}(\text{NH}_3)_4]_2\text{I}_2 \cdot 2\text{I}_2$. They also made some complexes with picric acid, and with *p*-dichlorobenzenesulphonic acid.

According to M. Adams,²⁰ when hydroxylamine is added to a conc. alcoholic soln. of cadmium iodide, the precipitate which is first formed redissolves, and when the soln. is allowed to stand, it deposits large, colourless, acicular crystals of **cadmium trihydroxylamine iodide**, $\text{CdI}_2(\text{NH}_2\text{OH})_3$. This compound is stable; soluble in both alcohol and water; and insoluble in ether. A comparison with the other double halides emphasizes the tendency of cadmium iodide to unite with three mols of hydroxylamine.

C. F. Rammelsberg prepared deliquescent crystals of **ammonium zinc tetra-iodide**, $2\text{NH}_4\text{I} \cdot \text{ZnI}_2$, by the evaporation of a mixed soln. of the component salts over sulphuric acid. H. Croft and E. Rimbach made deliquescent crystals of **ammonium cadmium tetraiodide**, $2\text{NH}_4\text{I} \cdot \text{CdI}_2 \cdot 2\text{H}_2\text{O}$, by evaporating a soln. of the component salts in theoretical proportions. J. M. Eder says that at 15° one part of the salt dissolves in 0.58 part of water; 0.7 part in alcohol of sp. gr. 0.794; 8.9 parts in ether of sp. gr. 0.729 and in 1.8 parts of ethereal alcohol. E. Tassilly, and H. Grossmann made $\text{CdI}_2 \cdot \text{NH}_4\text{I}$ by boiling cadmium hydroxide in a soln. of ammonium iodide, some $\text{CdI}_2 \cdot 2\text{NH}_3$ being formed at the same time. E. Tassilly said that the salt has $\frac{1}{2}\text{H}_2\text{O}$, H. Grossmann, H_2O , and E. Rimbach, that the salt is anhydrous, and is stable in water. J. M. Eder says that at 15° one part of the salt dissolves in 0.9 part of water; in 0.88 part of alcohol of sp. gr. 0.794; and in 2.4 parts of ether of sp. gr. 0.729. According to S. Lussana and G. Bozzola, the soln. of $\text{NH}_4\text{I} \cdot \text{CdI}_2$ has a maximum density at 3.54° .

H. Brand found the f.p. curve of mixtures of cadmium and sodium iodides has no signs of the formation of a compound, or of solid soln. There is a simple V-eutectic at 287° with 47 per cent. NaI. E. Cornec and G. Urbain measured the f.p., and F. Bourion and E. Rouyer the b.p., of soln. of mixtures of the alkali and cadmium iodides and obtained results in harmony with the composition of the known double salts. C. F. Rammelsberg prepared deliquescent crystals **sodium zinc tri-iodide**, $\text{NaI} \cdot \text{ZnI}_2 \cdot 3\text{H}_2\text{O}$, by the evaporation over sulphuric acid of a soln. of the component salts in theoretical proportions; the corresponding **sodium zinc tri-iodide**, $\text{KI} \cdot \text{CdI}_2$, was made in a similar way. H. Croft made **sodium cadmium tetraiodide**, $2\text{NaI} \cdot \text{CdI}_2 \cdot 6\text{H}_2\text{O}$, in a similar manner. J. M. Eder says that at 15° , one part of the salt dissolves in 0.63 part of water; in 0.86 part of alcohol of sp. gr. 0.794; and in 10.1 parts of ether of sp. gr. 0.729. H. Croft, and E. Rimbach made the corresponding **potassium cadmium triiodide**, $2\text{KI} \cdot \text{CdI}_2$, in a similar way. H. Brand found that the f.p. curve of mixtures of potassium and cadmium iodides, Fig. 44, has a eutectic at 185° and 47.5 molars per cent. of KI. The ascending branch of the curve has two breaks corresponding with the formation of **potassium cadmium tetraiodide**, $\text{CdI}_2 \cdot 2\text{KI}$, at 269° from crystals and liquid; and a transformation of the α -cubic crystals at 215° into the β -double refracting modification stable at low temp. E. Chauvenet, and G. Urbain's analysis of the thermal effect on mixing soln. agreed with the formation of potassium cadmium tetraiodide, $2\text{KI} \cdot \text{CdI}_2$; likewise also R. G. van Name and W. G. Brown's study of the equilibrium conditions of soln. of the component salts. F. W. Clarke's value for the sp. gr. of the salt at 21° is 3.359. One part of the clear deliquescent crystals, says J. M. Eder, dissolves at 15° in 0.73 part of water; in 1.4 parts of alcohol of sp. gr. 0.794; and in 34.5 parts of ether, of sp. gr. 0.729. The sp. gr. of soln. of the salt have been measured by O. Grotrian; the lowering of the f.p. of soln. of the salt, by H. C. Jones and F. H. Getman, and by H. C. Jones and B. P. Caldwell; the electrical conductivity by O. Grotrian, F. J. Wershoven, C. Immerwahr, and J. W. McBain; and the transport number by W. Hittorf. J. H. Walton says that like other soluble iodides K_2CdI_4 decomposes hydrogen peroxide with the evolution of oxygen.

FIG. 44.—Equilibrium Curves of Binary Mixtures of Cadmium and Potassium Iodides.

In passing along the series of bivalent metals from magnesium to zinc, cadmium, and mercury, the variety of double salts increases with the at. wt. of the metal; for example, mercury gives six types of double salt with caesium, and there are three with cadmium, two with zinc, and one with magnesium. The three **caesium cadmium tetra- and penta-iodides** with $\text{CsI}:\text{CdI}_2=3:1$, $2:1$, and $1:1$ were prepared by H. L. Wells and P. T. Walden like the corresponding bromides. Caesium cadmium iodide, $\text{CsCdI}_3 \cdot \text{H}_2\text{O}$, or $\text{CsI} \cdot \text{CdI}_2 \cdot \text{H}_2\text{O}$, is obtained in thin plates from a soln. with the component salts in the mol. proportions $1:1$. The two **caesium zinc tetra- and penta-iodides**, $3:1$ and $2:1$, were made by H. L. Wells and G. F. Campbell like the corresponding chlorides and bromides. The existence of the zinc salts $1:1$ was suspected in the syrupy liquid obtained by crystallizing the $2:1$ salt. In view of the fact that caesium usually forms more stable and less soluble double halides than the other alkali metals, it is remarkable that there should be a difficulty in preparing the $1:1$ type of caesium zinc halides when the

ammonium, sodium, and potassium zinc iodides, as well as the 1 : 1 caesium magnesium chloride and bromide, can be readily obtained.

According to G. Hermann, cuprous and cadmium iodides form a single series of solid soln. with a minimum in the m.p. curve at 350° and 90 per cent. of cadmium iodide. C. R. Rammelsberg made **barium zinc tetraiodide**, $\text{BaI}_2 \cdot \text{ZnI}_2 \cdot \text{H}_2\text{O}$, in a similar manner to the process employed for the potassium salt; and H. Croft made **barium cadmium tetraiodide**, $\text{BaI}_2 \cdot \text{CdI}_2 \cdot 5\text{H}_2\text{O}$; and H. C. Jones and B. P. Caldwell made **strontium cadmium tetraiodide**, $\text{SrI}_2 \cdot \text{CdI}_2 \cdot 8\text{H}_2\text{O}$, by evaporating a soln. of equi-mol. proportions of the component salts, and they measured the mol. conductivities of the soln.

§ 15. Zinc and Cadmium Sulphides

According to E. Schütz,¹ zinc has a greater affinity than lead for sulphur, but a smaller affinity than manganese, copper, nickel, iron, or tin; J. Fournet found the affinity of zinc for sulphur to be greater than that of lead, silver, antimony, or arsenic, and smaller than that of copper, iron, or tin; and E. Schürmann said the affinity of zinc for sulphur is greater than that of nickel, cobalt, iron, arsenic, thorium, or manganese; and he gives the order cadmium, antimony, tin, and lead. E. F. Anthon gives the order silver, copper, lead, cadmium, iron, nickel, cobalt, and manganese. A. L. Orłowsky also studied the affinity of the elements for sulphur. B. G. Bredberg assumed that some zinc ores contain zinc subsulphide, Zn_2S , but K. Friedrich added that this is not probable. There are no signs of the formation of zinc subsulphide when sulphur and zinc sulphide are melted together.

Zinc sulphide occurs in nature crystallized in two different forms—the one, the common zinc blende, or sphalerite crystallizes in the cubic system; and the other, the comparatively rare wurtzite, belongs to the hexagonal system. The purer forms of both are straw-coloured, although E. S. and J. D. Dana² state that specimens of blende from Franklin (New Jersey), and from Nordmark (Sweden) are white, and they have been called *cleiophane*. Although zinc blende is perhaps the most widely distributed mineral containing zinc, it does not appear to have attracted the attention of the early mineralogist. The mineral has a superficial resemblance to galena, except in its cleavage, but it yields no metal when smelted, and therefore it was called by G. Agricola, *galena inanis*, and by J. G. Wallerius, *pseudo-galena*. The German mining term *blende* was then employed from *blenden*, to deceive; and was also called by E. F. Glocker, *sphalerite*, from *σφαλερός*, deceptive. The presence of zinc in blende was first demonstrated by G. Brandt in 1735, and zinc was extracted from the mineral by A. von Swab in 1738. M. Malouin prepared zinc sulphide in 1743, and for a time it was thought to be different from the natural sulphide. T. Bergman analyzed phosphorescent blende in 1779. Analyses of zinc blende have been reported by J. A. Arfvedson, A. Löwe, C. Kersten, C. Kùhlemann, T. H. Henry,

J. L. Smith, T. Scheerer, E. Bechi, A. Breithaupt, L. Lecanu, P. Berthier, J. B. J. D. Boussingault, C. U. Shepard, A. Osann, J. Loczka, L. Sipöcz, W. Eitel, etc. Zinc blende containing gallium has been reported by L. de Boisbaudran, C. Rimatori, H. B. Cornwall, and J. B. Kirkland; mercury by P. Soltsien; tin by A. Stelzner and A. Schertel; indium by F. L. Bartlett; cadmium by C. Rimatori, A. Schmidt, A. Frenzel, and O. Herting; lead and manganese by O. Herting; cobalt by F. A. Genth; and rare earths by J. Strishoff, and S. Samailoff. F. Sandberger found lithium in the wurtzites but not in the blendes which he examined. W. N. Hartley and H. Ramage found spectroscopically iron, copper, silver, and traces of potassium and sodium in all the blendes they examined, and cadmium, gallium, indium, thallium, lead, nickel, chromium, and calcium in many other specimens.

The hexagonal variety of zinc sulphide, occurring in the silver mine, Oraro (Bolivia), was named by C. Friedel wurtzite, after A. Wurtz; the cadmiferous hexagonal blende from Pribram was named *pribramite* by J. J. N. Huot, and another variety *spiauterite*—from *spiauter*, spelter—by A. Breithaupt. Analyses of wurtzite have been made by A. Löwe, J. F. Malaguti and J. Durocher, J. Gerstendörfer, W. Stahl, H. Traube, etc. The mineral *voltzite* or *voltzine* is an oxysulphide, $\text{ZnO} \cdot 4\text{ZnS}$, found as a yellow incrustation at Pontgibaud, France, and at Joachimsthal, Austria. It is probably a mixture of oxide and sulphide. Hexagonal cadmium sulphide, *greenockite*, was found by R. Jameson at Bishoptown (Scotland), and named after Lord Greenock. This mineral was further investigated by A. Connell, A. Breithaupt, and W. Nicol; D. Forbes called it *cadmium blende*. Analyses of greenockite have been made by A. Connell, T. Thomson, A. K. Christomanos, and E. Schüler.

Zinc sulphide has been observed as a furnace product by J. F. L. Hausmann,³ B. von Cotta, W. Stahl, J. D. Robertson, C. C. von Leonhard, C. F. Plattner, C. W. C. Fuchs, J. H. L. Vogt, etc. J. J. Nöggerath and G. Bischof found some zinc sulphide a few inches in thickness deposited on the woodwork of an old lead mine; it is thought to have been formed by the reducing action of decaying wood upon zinc sulphate: H. A. Wheeler found blende in lignite; W. P. Jenney in coal; C. R. Keyes found blende crystals on iron nails immersed 15 yrs. in mine water; W. P. Jenny, J. D. Robertson, M. W. Iles and J. D. Hawkins also found deposits of blende in mines; and J. Delanour also observed a deposit of zinc sulphide from some spring water where it was probably formed by the reduction of zinc sulphate by organic matter.

The preparation of zinc and cadmium sulphides.—When zinc filings are heated with sulphur, the sulphur volatilizes before combination occurs, but J. Davy⁴ made a little white zinc sulphide by passing sulphur vapour over red-hot zinc. The m.p. of the product is high, and it forms a protective film on the surface of the particles of metal. T. Griffiths and J. Cawley passed zinc vap. into a chamber containing sulphur vapour at a higher temp. than the b.p. of that element. An intimate mixture of zinc dust and sulphur inflames when struck by a hammer. H. Schwarz, and A. Cavazzi converted zinc filings into sulphide by heating them in a stream of carbon disulphide vapour; W. Fränkel passed nitrogen charged with the vapour of carbon disulphide over red-hot zinc, and obtained zinc sulphide and carbon. J. J. Berzelius found zinc filings withdraw the sulphur from potassium polysulphide, and the reaction is explosive if heat be applied; he also made zinc sulphide by heating mercuric sulphide with zinc—the reaction is explosive, and the mercury volatilizes. J. C. C. Dehne, and C. M. Despretz heated zinc oxide with sulphur and obtained “un produit tellement identique avec la blende, que des minéralogistes exercés n’ont pu distinguer ces deux combinaisons l’une de l’autre.”

J. Milbauer gradually added zinc or cadmium oxide to molten potassium thiocyanate, and obtained amorphous zinc or cadmium sulphide. E. Weinschenk obtained an amorphous powder of cadmium sulphide by heating cadmium thiocyanate with acetic acid in a sealed tube for 4–5 hrs. at 238°–250°. E. T. Allen and J. L. Crenshaw found that zinc salts do not react with sodium thiosulphate in the

cold, but at 100° the zinc is quantitatively precipitated as amorphous sulphide: $4\text{Na}_2\text{S}_2\text{O}_3 + \text{ZnSO}_4 = 4\text{Na}_2\text{SO}_4 + \text{ZnS} + 4\text{S}$. Some sulphur dioxide, and hydrogen sulphide are formed by secondary reactions. J. Landauer obtained amorphous cadmium sulphide by heating cadmium oxide with anhydrous sodium thiosulphate in a sealed tube; F. Faktor heated dried cadmium chloride with sodium thiosulphate; and E. Donath treated a soln. of cadmium chloride or sulphate with ammonia, added an excess of acetic acid, and then treated the boiling soln. with sodium thiosulphate; after boiling for about half an hour, the cadmium was completely precipitated as sulphide admixed with free sulphur.

K. Brückner found that zinc sulphide is formed with the evolution of sulphur dioxide when anhydrous zinc sulphate and sulphur are triturated together. L. N. Vauquelin, and A. Violi obtained the sulphide by heating the anhydrous sulphate with sulphur, J. L. Gay Lussac washed the unreduced sulphate from the mass with water, or converted it into sulphide by another ignition with sulphur. P. Berthier reduced zinc sulphate by heating it with charcoal; if the temp. be too high, much oxide is formed. The oxide may be extracted from the sulphide by means of dil. hydrochloric acid.

E. T. Allen and J. L. Crenshaw obtained the amorphous sulphide by the action of hydrogen sulphide on zinc carbonate and hydrocarbonate; by heating amorphous zinc sulphide with sodium hydrocarbonate, P. Farup⁵ obtained coarse flecks of zinc sulphide, which could be easily filtered, by the action of hydrogen sulphide on a soln. of a zinc salt containing some hydrogen peroxide, and warming for 4 or 5 mins. to 60° or 70° . Zinc sulphide is precipitated from soln. of zinc cyanide by hydrogen sulphide; and A. Vita precipitated zinc as sulphide from ammoniacal soln. of certain low-grade zinc ores. E. T. Allen and J. L. Crenshaw found that the precipitate obtained by adding alkali sulphides to a soln. of a zinc salt in the cold, or at a boiling temp., is always amorphous; but if conc. soln. of alkali sulphides are employed at a higher temp., sphalerite is obtained—wurtzite is never formed. With cadmium salts under similar conditions no crystalline product was obtained, although with ammonium sulphide crystals of greenockite were formed. V. Bermont used sodium sulphide as the precipitating agent with an ammoniacal soln. of a zinc salt; and W. Minor with an ammoniacal soln. of a cadmium salt. H. W. de Stucklé precipitated zinc sulphide from soln. of barium zincate by barium sulphide, and from soln. of alkali zincate by alkali sulphide. J. T. Norton heated soln. of zinc sulphate with sodium thiosulphate at 140° to 200° , and obtained a mixture of sulphur and zinc sulphide; and M. le Blanc and K. Schick obtained zinc sulphide by the alternating current electrolysis of a soln. of sodium thiosulphate between zinc electrodes. R. Lorenz obtained cadmium sulphide by the electrolysis of a soln. of an alkali chloride, nitrate, or sulphate between a cupric sulphide cathode and a cadmium anode; M. le Blanc also experimented on this subject.

H. de Sénarmont,⁶ and H. Baubigny prepared sphalerite by heating a soln. of a zinc salt with hydrogen sulphide in a sealed tube; and J. Durocher, by heating zinc chloride in a stream of hydrogen sulphide. E. T. Allen and J. L. Crenshaw obtained only the amorphous sulphide by this process, but they obtained good crystals of sphalerite by heating amorphous zinc sulphide in a soln. of sodium sulphide at 350° in a steel bomb; the same mineral was obtained in acid soln.—*vide* wurtzite—sphalerite is alone formed in alkaline soln.; here again E. T. Allen and J. L. Crenshaw obtained only the amorphous sulphide. A. Villiers obtained crystalline zinc sulphide by heating amorphous zinc sulphide, precipitated from a feebly alkaline soln., for one minute between 70° and 100° ; by adding ammonium chloride to amorphous zinc sulphide as precipitated from an alkaline soln.; and by freezing an alkaline soln. in which amorphous zinc sulphide is suspended. Sphalerite crystallizes from a soln. of zinc sulphide in molten sodium chloride and potassium polysulphide, provided the temp. be below 1020° ; thus, P. Hautefeuille stated that blende is transformed into wurtzite when heated to redness, and he heated zinc or cadmium sulphide covered with a layer of alumina in a graphite crucible; the

wurtzite or greenockite crystallized on the alumina. A. Mourlot crystallized zinc sulphide by heating it in an electric arc furnace. F. Beijerinck transformed amorphous into crystalline cadmium sulphide by heating it in a sealed glass tube. J. J. Berzelius, and H. Rose heated precipitated zinc sulphide in a stream of hydrogen sulphide. O. Rohde found amorphous zinc sulphide becomes crystalline when subjected to a press. of 8000 atm.—*vide* the action of sulphur on zinc. H. St. C. Deville and L. Troost fused together equal parts of zinc sulphate, calcium fluoride, and barium sulphide, and obtained crystals of wurtzite; with cadmium sulphide in place of zinc sulphate, crystals of greenockite were formed. They also prepared wurtzite by passing hydrogen over red-hot zinc or cadmium sulphide; the sulphide was decomposed, and redeposited in a crystalline form in the cooler parts of the tube as the hydrogen sulphide and zinc recombined; W. Biltz used an atm. of nitrogen. R. Lorenz obtained crystals of wurtzite and greenockite by acting on the vapour of zinc or cadmium with hydrogen sulphide. T. Sidot prepared wurtzite or greenockite by heating zinc or cadmium oxide in the vapour of sulphur; and he found wurtzite is formed when amorphous zinc sulphide is heated in an atm. of nitrogen, or sulphur dioxide. A. Gautier passed the vapour of carbon disulphide over heated zinc oxide; the experiments did not succeed when other zinc salts were used, or when carbonyl sulphide was employed.

E. Schüler, and R. Schneider prepared crystals of wurtzite and greenockite by fusing precipitated zinc or cadmium sulphide with potassium carbonate and sulphur. M. J. Fordos and A. Gélis, and C. Geitner heated metallic cadmium with sulphurous acid in a sealed tube at 200°, and obtained a mixture of amorphous and crystalline cadmium sulphide. E. T. Allen and J. L. Crenshaw obtained only amorphous zinc sulphide by the action of metallic zinc on sat. sulphurous acid. J. Uhl heated cadmium to redness in a stream of sulphur dioxide and obtained a mixture of cadmium sulphate and the crystalline sulphide. A. Ditte dissolved amorphous cadmium sulphide in ammonium hydrosulphide, at 60°, and obtained crystals of greenockite and free sulphur on cooling. V. Stanek heated zinc sulphide with ammonium sulphide in a tube at 150° to 200°, and obtained crystals of sphalerite, but E. T. Allen and J. L. Crenshaw succeeded in making only the amorphous sulphide; with cadmium and ammonium sulphides, in a sealed tube at 150°–200° for 3 days, greenockite crystals were formed. H. Viard prepared crystalline zinc and cadmium sulphides by passing a stream of carbon dioxide charged with the vapour of zinc or cadmium chloride over red-hot stannous sulphide. E. T. Allen and J. L. Crenshaw obtained wurtzite by subliming zinc sulphide between 1200° and 1300°, and also by the action of hydrogen sulphide derived from sodium thiosulphate, on acid soln. of zinc sulphate at 250°; similarly, also with soln. of cadmium sulphate. They obtained crystals of greenockite by heating amorphous cadmium sulphide with 30 per cent. sulphuric acid in a sealed tube for 2 days at 200°.

Zinc sulphide was found by E. Schürmann to be precipitated before nickel, cobalt, iron, arsenic, thorium, or manganese by incompletely saturating a hot $\frac{1}{10}N$ -soln. of a zinc salt by hydrogen sulphide; J. C. A. Meyer observed that hydrogen sulphide precipitated iron and lead sulphides before the zinc sulphide from an acetic acid soln. of iron, lead, and zinc salts. W. Büddeck precipitated zinc sulphide alone from lye containing iron (ic), cobalt, nickel, and manganese either by the action of hydrogen sulphide, or of a sulphide and acid. J. Lefort and P. Thibault found that the presence of gum arabic in soln. of zinc salts hinders the precipitation of zinc sulphide by hydrogen sulphide.

In the analytical classification of elements, zinc is included in the group of elements which are not precipitated from acid soln. by hydrogen sulphide. If a current of this gas be passed into a sat. soln. of zinc chloride, part of the metal is precipitated as sulphide and hydrochloric acid is formed: $ZnCl_2 + H_2S = ZnS + 2HCl$, so that the soln. becomes acid; when the acid has attained a certain conc., the action apparently ceases. The reaction, indeed, is reversible. No precipitation occurs if over 4 c.c. of hydrochloric acid of sp. gr. 1.12 be present per 100 c.c. of soln.

According to H. Baubigny, the accumulation of hydrochloric acid can be prevented by the use of salts of certain organic acids—ammonium or sodium formate, acetate, etc. These substances react with the hydrochloric acid, producing sodium or ammonium chloride and the corresponding organic acid. The solubility of zinc sulphide in these organic acids is small enough to be neglected in certain analytical operations. According to S. Glixelli, the action of hydrogen sulphide on zinc salts does not depend on the balanced reaction: $\text{ZnCl}_2 + \text{H}_2\text{S} \rightleftharpoons \text{ZnS} + 2\text{HCl}$. He said the reaction is not reversible, but a kind of false equilibrium occurs in acid soln. L. Bruner, and G. Bruni and M. Padoa showed that the precipitated zinc sulphide may change into a less soluble form when it has been allowed to stand for some time. For the more soluble α -ZnS, in acid soln., S. Glixelli found $K[\text{H}]^2 = [\text{Zn}]^2[\text{H}_2\text{S}]$, where $K = 45 \times 10^{-4}$; and for the less soluble β -ZnS precipitated from alkaline soln., $K = 1 \times 10^{-2}$. L. Bruner and J. Zawadzky considered that these numbers cannot be exactly determined because of the rapidity of the change α -ZnS \rightarrow β -ZnS. S. Glixelli found that the state of false equilibrium was favoured by the presence of silicic acid, zinc, cadmium or copper sulphide. G. Bruni and M. Padoa found that if air or hydrogen be passed through the liquid from which cadmium sulphide has been precipitated by hydrogen sulphide, the precipitate redissolves. S. Glixelli was able to obtain precipitates from rather conc. acid soln. provided sufficient time be allowed. E. T. Allen and J. L. Crenshaw have plotted the conc. of zinc in soln. as they vary with the conc. of the sulphuric acid, after precipitation with hydrogen sulphide at one atm. press. has ceased; the results are shown in Fig. 45, where the shaded portion represents the zinc remaining in soln. This subject is rather important in analytical work, when zinc is precipitated as sulphide from faintly acid soln. It has been discussed by C. W. Eliot and F. H. Storer, E. Grundmann, F. C. Calvert, etc. H. A. Fales and G. M. Ware show that the least error occurs when the acidity of the soln. represented in terms of the conc. of the H^+ -ion is between 10^{-2} and 10^{-3} . This is illustrated in Fig. 46, where the ordinates represent

FIG. 45.—The Effect of Free Sulphuric Acid on the Precipitation of Zinc Sulphide.

FIG. 46.—Effect of Concentration of Hydrogen Ion on the Precipitation of Zinc as Sulphide.

the average error produced when zinc sulphide is precipitated from 200 c.c. of a soln. containing a gram of ammonium zinc sulphate, $\text{Zn}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$. If the conc. of the H^+ -ion exceeds 10^{-2} the completeness of the precipitation rapidly falls, and if the conc. of the H^+ -ion is less than 10^{-3} , the precipitate becomes slimy and difficult to filter. The favourable conc. of H^+ -ion is obtained conveniently by using ammonium formate, or citrate. E. T. Allen and J. L. Crenshaw also found that the zinc sulphide precipitated from neutral or acid soln. at temp. below 200° , is always amorphous; and observations on the influence of temp. and acidity of soln. on the crystalline form of zinc sulphide are summarized in Table IV, where *W* represents wurtzite, *S* sphalerite, and *A* the amorphous form of zinc sulphide. A. L. T. Mösveld also found that in acid soln. wurtzite is precipitated, and in neutral or faintly alkaline soln., sphalerite separates.

TABLE IV.—THE EFFECT OF TEMPERATURE AND ACID CONCENTRATION ON THE CRYSTALLINE FORM OF ZINC SULPHIDE.

Temp.	Percentage amount of H_2SO_4					
	1.0	2.5	4.0	5.0	7.5	10.0
250°	<i>S</i> and <i>W</i>	<i>W</i> and <i>A</i>	—	<i>W</i> and <i>A</i>	—	—

350°	—	70% <i>W</i>	—	30% <i>W</i>	—	80% <i>W</i>

The conditions of temp. and final acid conc. necessary for the genesis of either form of zinc sulphide are illustrated in Fig. 47. A. Kohner found that cadmium sulphide, precipitated from neutral soln., always contained some free sulphur, and R. Meldrum obtained amorphous cadmium sulphide from neutral soln. of cadmium salts, even after standing for a long time, or after boiling; and E. Donath and J. Mayrhofer obtained only amorphous cadmium sulphide with alkali sulphide as precipitating agent. E. A. Partridge studied the preparation of pure cadmium sulphide from cadmium sulphate and hydrogen sulphide.

G. Bruni and M. Padoa, and H. Baigny found that by raising the press. of the hydrogen sulphide the equilibrium

$H_2S + ZnCl_2 \rightleftharpoons 2HCl + ZnS$ was displaced in favour of the right side. Similarly with cadmium salts. Acidified soln. of cadmium sulphate which precipitate cadmium sulphide when treated with hydrogen sulphide at ordinary press., give no precipitate if the gas be under reduced pressure. M. Padoa and L. Cambi obtained the results indicated in Table V, where the number in the press. column

represents the smallest press., in mm. of mercury, which is required for the production of cadmium or zinc sulphide. W. N. Stull found the reaction between hydrogen sulphide and hydrochloric or sulphuric acid soln. of zinc salts is exceedingly slow, and in no case was equilibrium attained after the soln. had been treated many hours with a rapid stream of the gas. The course of the reaction in either case is virtually the same. Agitation had no appreciable influence on the results; and a difference of temp. between 20° and 50° had very little influence. Similar results were obtained with a soln. of cadmium salts in sulphuric or hydrochloric acid; the crystallinity of the precipitate depends on the acidity of the soln., the temp., etc.

T. Sidot⁷ synthesized **phosphorescent zinc sulphide**—*Sidot's blende*—by heating crystalline zinc sulphide for 4 or 5 hrs. in a porcelain tube in a stream of sulphur dioxide; C. Henry made it in large quantities by precipitating a neutral soln. of pure zinc chloride with ammonia, redissolving the precipitate in excess of ammonia, and then exactly precipitating with hydrogen sulphide. The precipitate is carefully washed and dried, and is then heated almost to a white heat in a fire-clay crucible placed inside a plumbago crucible, brasqued with charcoal. The brilliancy of the phosphorescence seems to depend on the purity of the zinc sulphide, and the product is either non-phosphorescent or feebly phosphorescent if zinc oxide or any zinc salt other than the chloride is used, or if alkali sulphides are used as the precipitant in place of hydrogen sulphide. Manganese sulphate, lead acetate, lithium carbonate, thallium carbonate, strontium chloride, basic bismuth nitrate, etc., all prevent phosphorescence. K. A. Hofmann and W. Ducca made it by C. Henry's process from commercial zinc chloride, but not from chemically pure zinc ammonium sulphate. If 5 grms. of sodium chloride and 0.2–0.5 gm. of magnesium chloride are added to 20 grms. of pure zinc ammonium sulphate dissolved in 400 c.c. of water, and the precipitate, with hydrogen sulphide, is dried without being washed, the yellow, crystalline zinc sulphide, which remains after heating, is highly phosphorescent. Contrary to C. Henry's statement, the phosphorescence must be due to the presence of traces of the sodium and magnesium salts. The addition of sodium chloride or of magnesium chloride alone does not cause the phosphorescence. The presence of traces of iron, nickel, cobalt, bismuth, chromium, or copper salts diminishes, but traces of salts of tin, selenium, manganese, or cadmium increase the effect. According to H. Grüne, pure zinc sulphide is not phosphorescent, but the addition of a trace of copper, silver, lead, bismuth, tin, uranium, or cadmium causes it to become so. Copper produces the best result, 1 part of copper in 10,000 causing a beautiful green phosphorescence. The addition of manganese, on the other hand, produces a yellowish-red phosphorescence, and the zinc sulphide in this case, when scratched or rubbed, emits light spontaneously. W. P. Jorissen and W. E. Ringer found the results obtained with zinc sulphide resembled those with the sulphides of the alkaline earths. The pure sulphide of cadmium, barium, or zinc does not phosphoresce except in the presence of traces of foreign matter such as bismuth salts. In the case of zinc sulphide, it is found that whereas magnesium chloride or sulphate has no action, bismuth, cadmium, or manganese salts and the chlorides of sodium or potassium produce a marked effect. The phosphorescence caused by the two latter substances is increased by the addition of manganese salts, is diminished by copper salts, and is entirely suppressed by platinum and silver salts.

A. Karl heated a mixture of manganese nitrate with five times its weight of zinc sulphide in an electric furnace at 1200° , the cold mass was washed in water and dried. The manganese nitrate can be replaced by stannic oxide, titanin oxide, silica, zirconia, didymium oxide, manganese silicate or stannate, etc. The product is strongly triboluminescent; with zinc sulphide alone, it is feebly so. K. Albert found that by calcining zinc sulphide with sodium chloride a phosphorescent product is formed which is not removed by washing; if heated with alkali sulphides, polysulphides, or hydrosulphides, the sensitiveness is diminished. H. W. de Stucklé

said that zinc sulphide becomes insensitive to light if the precipitated sulphide is dehydrated so that the ratio $\text{H}_2\text{O} : \text{ZnS}$ is no more than 1 : 5. J. Cawley found the precipitate obtained by the addition of alkaline earth sulphides to soluble zinc salts, when calcined, washed, and powdered, is phosphorescent. J. Schmidt, and E. Tiede and A. Schleede described the preparation of highly phosphorescent zinc sulphide.

The physical properties of zinc and cadmium sulphides.—The colour of zinc sulphide is white or pale yellow (if cadmiferous). Sphalerite is white when pure, but when ferruginous, it is variously coloured, yellow, brown, or black. Wurtzite is usually brown, but when prepared artificially it is colourless. Amorphous cadmium sulphide is coloured yellow, orange, or brown. According to E. T. Allen and J. L. Crenshaw,⁸ fresh rapidly precipitated zinc sulphide has spherical particles 0·0002 to 0·0005 mm. diameter; while the particles of the slowly precipitated sulphide increase in size, and aggregate into clusters or crusts when allowed to stand in the soln. When the aggregates are compressed under a cover glass, they flatten and break open like a stiff jelly. The jelly-like globules contain very little water, the crusts and globules may harden and become brittle and gritty, and exhibit a refractive index for Li-light between 2·18 and 2·25, which is smaller than the refractive index of sphalerite or wurtzite. The double refraction exhibited by the amorphous sulphide is probably caused by strains induced in non-homogeneous masses during the process of hardening. When heated above 200°, the amorphous crusts and globules become wholly or partially crystalline. Amorphous cadmium sulphide has not been observed in a hard, brittle, doubly refracting form like zinc sulphide, and when it exhibits double refraction, its refractive index approaches that of greenockite.

Cadmium sulphide is used as a paint—*cadmium yellow*, *Cadmiumgelb*, *jaune de cadmium*—varying in colour from lemon-yellow to a deep orange. Admixtures of cadmium yellow and white-lead are known in commerce as *jaune brillant*. This colour is inclined to darken owing to the formation of black lead sulphide. According to O. Follenius, the different tints are due to the presence of variable amounts of impurity, but G. Buchner claimed that this hypothesis cannot be right because samples with variable amounts of impurity may have the same tint; and samples of different tint may have the same amount of impurity. G. Buchner, and N. von Klobukoff hold that the differences in colour are due to the existence of two modifications—one, α -**cadmium sulphide**, is lemon-yellow, the other, β -**cadmium sulphide**, is vermillion; the latter is assumed to be a polymeride of the former, and variations in the colour of cadmium sulphide are due to admixtures of these two forms in different proportions. The yellow variety is said to be readily polymerized into the red variety by dil. acids and alkalis; hence, on precipitating soln. of cadmium salts with hydrogen sulphide, at first the yellow sulphide forms, but, as the liberated acid comes into action, the red sulphide is precipitated, and if the soln. is acid beforehand, little or no yellow sulphide is produced. The red variety passes through the yellow stage when dissolved in acids. Sodium sulphide produces the yellow sulphide in dil. soln. of a cadmium salt, a reddish precipitate in strong soln., and a brick-red one in boiling soln. Polysulphides of potassium or ammonium precipitate the yellow cadmium sulphide mixed with varying quantities of finely divided sulphur, which can be extracted by carbon bisulphide. N. von Klobukoff found (i) the sp. gr. of the yellow varieties to vary from 3·906 to 4·147, and that of red varieties from 4·476 to 4·513; (ii) the yellow variety to be hexagonal—the red has not been determined with certainty, but shows regular and monoclinic forms; and (iii) the yellow to change to red under the influence of friction, press., heat, chemical agents, etc.

The crystals of cadmium sulphide are yellow when in tufts of hair-like needles, but larger crystals are brownish-yellow. The different colours of amorphous cadmium sulphide are due to the relative amounts of light transmitted and reflected, since the colour of a substance by reflected light depends on the character and relative amounts of light reflected directly from the external surfaces, and indirectly from internal surfaces—i.e. after having passed into the substance and been reflected

out. Greenockite absorbs the blue and violet and part of the green spectral rays, the remainder are freely transmitted; a comparatively large amount of blue light is directly reflected by the plane bright faces of the crystals about 1 mm. in diameter, and a small amount of red, orange, yellow, and green is reflected after passing through the surface layer. The combined effect of all the reflected light is a lustrous dark yellow to yellowish-green or dark citron-yellow. Crystals 0.01 mm. in diameter reflect about the same amount of blue light directly, and much more of that which has penetrated the surface so that the resulting colour is a brilliant yellow. Massed crystals with a dull surface have a light yellowish-brown or citron colour. The grains of powdered crystals usually have bright but not plane surfaces and give a brilliant orange powder, for there is less direct reflection, and more indirect reflection of light from the interior which has lost more green and yellow than with a powder having plane-faced fragments. The colour of the amorphous sulphide is explained in a similar manner. The amorphous sulphide absorbs more strongly in the yellow and green and, by transmitted light, its colour is orange-yellow in films 0.01 mm. thick, and yellow in films 0.001 mm. thick. The powdered amorphous sulphide with grains 0.0001 to 0.001 mm. in diameter is bright yellow with a tinge of orange, and with grains 0.004 to 0.007 mm. in diameter, or compact aggregates of smaller globules, is bright orange. According to E. T. Allen and J. L. Crenshaw, a soln. of about 200 c.c. of water, 4 grms. of sodium sulphate, 10 grms. of sodium thiosulphate, and 2 grms. of cadmium sulphate was boiled for some hours, and hot water added from time to time. The particles of the lemon-yellow precipitate obtained after an hour's boiling were too small to measure; but after $2\frac{1}{2}$ hrs.' boiling the particles were 0.001 mm. in diameter; as the boiling continued, the particles became darker and darker until the precipitate had acquired a dark orange colour, and the particles ranged up to 0.05 mm. in diameter. The light yellow precipitate formed by the action of ammonium sulphide on a cadmium salt retains the same colour after it has been heated so as to produce crystalline greenockite; and the latter becomes orange coloured when ground in a mortar. Hence, the difference in colour is not due to a difference in crystalline form. The difference in the sp. gr. of the two forms is due to the variation in the sp. gr. of intermixtures of different proportions of the crystalline and amorphous sulphides, to the presence of occluded salts, and to the errors involved in the determination of the sp. gr. of very fine powders. There is no reliable evidence that cadmium sulphide crystallizes in more than one form; the different colours of cadmium sulphide are due to differences in the size of the grains; and G. Buchner and N. von Klobukoff's hypothesis is unnecessary.

The **crystals** of zinc sulphide are dimorphous, belonging either to the cubic system—sphalerite—or to the hexagonal system—wurtzite—and, according to C. Friedel, the axial ratio is $a:c=1:0.8175$. The crystals of zinc sulphide have been studied by A. Sadebeck, F. Becke, J. Nölting, P. Groth, G. vom Rath, A. Franzenau, C. A. Kenngott, C. Klein, A. Lacroix, C. Friedel, H. Förster, E. Döll, H. A. Miers, etc. Cadmium sulphide exhibits only the hexagonal form—greenockite—with the axial ratio $a:c=1:0.8109$. The crystals of cadmium sulphide have been studied by A. Breithaupt, N. von Kokscharoff, O. Mügge, R. P. Greg and W. G. Lettsom, M. F. Heddle, H. Viard, F. Rinne, G. T. Prior, E. Schüler, R. Schneider, W. Biltz, etc. E. T. Allen and J. L. Crenshaw stated: "We have crystallized cadmium sulphide by every method we could devise, and have obtained greenockite in every case"; no cubic modification, analogous with zinc sulphide, has yet been prepared; poorly developed twins of greenockite may represent the supposed monoclinic modification of cadmium sulphide. The cubic modification of zinc sulphide crystallizes in the form of distorted dodecahedrons at about 800° from molten sodium chloride; as a mixture of dodecahedrons and tetrahedrons about 0.01 mm. diameter at 300° from a conc. soln. of sodium sulphide; and in tetrahedrons alone when kept at 200° for 11 days in a similar soln. The hexagonal form of zinc sulphide appears in prismatic, hemimorphic crystals strongly striated

across the prism faces; in crystals tabular parallel to the base and modified by a different pyramid on each end; and the hardened amorphous globules from coherent masses of small doubly refracting grains of wurtzite—radial forms like schalen blende may appear. Wurtzite prepared by sublimation may appear in slender needles, or stout prisms. The hexagonal crystals of artificial greenockite were prismatic, with parallel extinction. The sublimate contains filaments and needles, stubby prisms, and twins after 1011, and after 2023. The **X-radiogram** and the space-lattice⁹ of zinc sulphide have been previously considered (Fig. 78, 1. 11, 8). That of sphalerite has been considered by W. H. and W. L. Bragg, and M. L. Huggins; and that of wurtzite, by W. L. Bragg, and M. L. Huggins. The latter also considered the relation of the space-lattices to the cleavages of these two forms. The crystals of cadmium sulphide and of wurtzite are isomorphous, and, like zincite, their symmetry is of the dihexagonal polar type. The axial ratio is nearly the same for all three compounds; $a:c$ for ZnO is 1:1.608, for ZnS, 1:1.635, and for CdS, 1:1.632. The close-packed structure has $a:c=1:1.632$. In the zinc blende form of zinc sulphide the structure is cubic, and W. L. Bragg adds:

In zinc oxide the zinc atoms are arranged on a face-centred cubic lattice, of side 5.41 Å. The oxygen atoms are on a similar lattice, derived from the former by a movement of translation which brings each oxygen atom into the centre of four zinc atoms arranged on the corners of a regular tetrahedron. The trigonal axes in zinc blende are polar. If the structure of wurtzite is the same as that of zinc oxide, as would appear to be the case, then in the crystals, both of zinc blende and wurtzite, every atom of sulphur is surrounded by four atoms of zinc at the corners of a regular tetrahedron, and every atom of zinc by four sulphur atoms similarly arranged. The dimensions of the structures are also almost identical. In wurtzite, for example, the distance between neighbouring zinc atoms is 3.85 Å., in zinc blende it is 3.83 Å. The nearest approach of the atoms is 2.35 Å. (R. N. Pease gave 2.41 Å.). The arrangement of the planes parallel to the plane (0001) of wurtzite is the same as that of the planes (111) in zinc blende, the axis perpendicular to the planes being in each case polar.

W. P. Davey found that cadmium sulphide exhibits the tetrahedral hexagonal lattice with sides 4.16 Å., and the nearest approach of the atoms 2.54 Å. The subject has been studied by G. Ewald, M. L. Huggins, and B. Quarder. The passage from the amorphous to the crystalline state of zinc and cadmium sulphides has been studied by F. Haber.

The crystals of greenockite may exhibit a very faint **pleochroism**, because the ordinary ray is more strongly absorbed in the green than the extraordinary ray. In white light the pleochroism of single crystals of cadmium sulphide is not perceptible, but in thin twin crystals it is seen by contrast in the two parts. E. T. Allen and J. L. Crenshaw studied the triangular **corrosion figures** of sphalerite produced by zinc chloride, and they correlated the changes in the optical properties, volume, and energy content of crystals of sphalerite and wurtzite; and J. Beckenkamp has discussed the close crystallographic relationship. F. Becke, and J. J. Krenner studied the corrosion figures of zinc blende with soln. of alkali hydroxides or carbonates; and G. Wulff, the cleavage.

C. J. B. Karsten¹⁰ gave 3.9235 for the **specific gravity** of zinc sulphide; the reported values for sphalerite or zinc blende range from F. A. Genth's 4.033 to C. Kuhlemann's 4.07. J. Joly found from 4.020 to 4.082 for zinc blende 15°/4°. E. Madelung and R. Fuchs gave 4.0904–4.0946 (0°) for zinc blende, and 4.0648 (0°) for wurtzite. E. T. Allen and J. L. Crenshaw gave 4.102 at 25° (water at 4° unity) for the sp. gr. of sphalerite, and 4.087 at 25°/4° for the sp. gr. of wurtzite, so that the sp. gr. of the two minerals of identical composition are nearly the same, but the sp. gr. of wurtzite is very slightly lower. They also found for ferruginous sphalerites:

	Sonora (Mexico).	Scotland.	Guipuzcoa (Spain).	Queensland.	Breitenbrunn (Saxony).
Per cent. iron	0.15	1.43	5.47	10.8	17.06
Sp. gr. 25°/4°	4.090	4.079	4.030	3.98	3.935
Sp. vol.	0.2444	0.2451	0.2481	0.2513	0.2541

E. Schüller gave 4.5 for the sp. gr. of artificial cadmium sulphide; and for greenockite, C. J. B. Karsten gave 4.605; H. J. Brooke, 4.80; A. Breithaupt, 4.908; A. K. Christomanos, 4.77; A. Connell, 4.842; and A. Mourlot, 4.8. According to E. T. Allen and J. L. Crenshaw, the sp. gr. of a sample of greenockite with 0.086 per cent. of lead, and 0.002 per cent. of iron, was 4.820 at $25^{\circ}/4^{\circ}$, and it is believed that most of the reported numbers are too high. The sp. gr. of the supposed polymerized forms of cadmium sulphide are indicated above. The **hardness** of zinc blende is given as varying from 3.5 to 4.0; of wurtzite, 3.0 to 4.0; and of greenockite, a little over 3. This subject was discussed by A. Reis and L. Zimmermann. R. Frankenheim, and A. Baumgartner and A. von Ettingshausen found a maximum hardness on the dodecahedral surface corresponding to the largest diagonal, and a minimum on the surface of the smallest diagonal of zinc blende. F. Exner, E. Pfaff, and G. Cesaro also studied the hardness of the crystals of zinc blende. E. Madelung and R. Fuchs gave for the **compressibility** of zinc blende 1.28×10^{-6} to 1.29×10^{-6} , and for that of wurtzite 1.34×10^{-6} megabars per sq. cm. K. Försterling studied the elastic constants of zinc blende.

H. Kopp¹¹ measured the **coefficient of thermal expansion** of zinc blende, and found 0.000036 ± 0.000002 between 15° and 47° ; and for a black variety, 0.000047 ± 0.000006 . H. Fizeau gave 0.00000670 at 40° , or at θ° , $0.00000619 + 0.000000128\theta$. A. S. Herschel and G. A. Lebour found the **thermal conductivity** of zinc blende with 28 per cent. of quartz to be 0.08 C.G.S. unit. F. E. Neumann found the **specific heat** of different specimens of zinc blende to be 0.1132, 0.1148, 0.1156; H. V. Regnault, 0.12303 between 15° and 98° ; H. Kopp found a black variety to have the sp. ht. of 0.120 between 16° and 46° ; J. Joly, 0.1159 between 10° and 100° ; G. Lindner found 0.1146 at 100° ; 0.1153 at 200° ; 0.1162 at 300° ; and 0.1167 at 350° . K. Bornemann and O. Hengstenberg found the sp. ht. of zinc blende rises from 0.1249 at ordinary temp. to 0.1351 at 900° . The sp. ht. of the zinc-iron blends suggest a reciprocal solubility of ferrous and zinc sulphides. Between 720° and 760° , the iron-zinc blends show two transition points indicating allotropic forms. K. Försterling studied the sp. ht. of zinc blende.

According to E. T. Allen and J. L. Crenshaw,¹² when cadmium sulphide is heated, its colour becomes progressively darker, until, at about 800° – 900° , it is dark red; on cooling, the sulphide returns to its former colour. Amorphous cadmium sulphide crystallized in two days at 450° . According to J. Weber, when isotropic sphalerite is heated in a Bunsen's flame, and cooled quickly, it becomes anisotropic; W. Biltz stated that when heated sphalerite changes to wurtzite without sublimation; and F. Beijerinck transformed sphalerite into wurtzite by heat. E. T. Allen and J. L. Crenshaw found that an enantiotropic change occurs at the **transition temperature**, $1020^{\circ} \pm 5^{\circ}$, when sphalerite or β -zinc sulphide changes to wurtzite or α -zinc sulphide. The former is stable below and the latter above the transition temp.; nevertheless, both forms may be crystallized at comparatively low temp. from aq. soln. Zinc sulphide is very difficult to crystallize at temp. below 200° , and neither form of zinc sulphide has been obtained in the wet way by J. Weber or E. T. Allen and J. L. Crenshaw. The change from wurtzite to sphalerite is sluggish so that it is easy to cool the former to atm. temp. without any transformation; it required 66 hrs. between 800° and 900° to change sphalerite entirely into wurtzite; and it required 48 hrs. between 850° and 900° , and 40 hrs. between 850° and 950° . The presence of ferrous sulphide lowers the transition temp.; thus:

Per cent. of iron . . .	0.15	1.43	5.47	10.8	17.06
Transition temp. . .	1020°	998°	955°	919°	880°

Wurtzite changes into sphalerite more rapidly when heated in a bath of molten sodium chloride than when heated in vacuo, or in an atm. of hydrogen sulphide—there are also signs of the reaction $2\text{NaCl} + \text{ZnS} = \text{Na}_2\text{S} + \text{ZnCl}_2$. The accelerating influence of an acid on the transformation of wurtzite to sphalerite is illustrated by Fig. 48. G. Buchner, N. von Klobukoff, R. Lorenz, and F. Beijerinck have reported

crystalline forms of cadmium sulphide other than greenockite. The last-named mineral is the only natural crystalline form of cadmium sulphide. E. T. Allen and J. L. Crenshaw studied the heating curves of cadmium sulphide, and also the various modes of preparation in the quest for a second crystalline form, but the results were negative. R. Cussak stated that the **melting point** of zinc blende or sphalerite is 1049° , and K. Friedrich, about 1660° ; but no other observer has been able to confirm this, although many have observed that the **sublimation temperature** or the temp. at which zinc sulphide volatilizes is near 1000° . Although cadmium and zinc sulphides sublime without melting, E. Tiede and A. Schleede found that zinc sulphide melts between 1800° and 1900° when heated under 100–150 atm. press. in an atm. of nitrogen, and the cold mass of wurtzite has a light greenish-yellow lustrous appearance; cadmium sulphide melts at about 1750° at 100 atm. press. The cold mass was a dark brownish-yellow lustrous solid. H. St. C. Deville and L. Troost stated that zinc blende does not volatilize at a white heat; T. Sidot, P. Hautefeuille, A. Mourlot, A. Ditte, A. Lodin, J. Percy, and K. Friedrich observed the slight volatility of the oxide, and C. Zenghelis stated that zinc sulphide is more volatile than the oxide. F. O. Doeltz and C. A. Graumann found that zinc blende and artificial zinc sulphide are but slightly volatile at 1000° , but copiously at 1200° ; and, according to W. Biltz, zinc blende begins to sublime at $1178^{\circ} \pm 2^{\circ}$, and wurtzite, at $1185^{\circ} \pm 6^{\circ}$. E. T. Allen and J. L. Crenshaw observed no melting under any circumstances when zinc sulphide is heated at atm. press.; dipping a tube containing zinc sulphide quickly into a furnace at 1550° gave a negative result. H. Rose noted that cadmium sulphide cannot be heated in a stream of hydrogen without loss; H. N. Morse and J. White found that cadmium sulphide can be sublimed more readily than zinc sulphide, and that both sulphides sublime undecomposed when heated to redness, with their respective metals. The action is similar to the phenomenon observed with the oxides, and is not due, as first supposed, to dissociation, but is purely mechanical and occurs when powdered porcelain is used in place of the metals. W. Biltz found that sublimation occurs at 980° ; and F. Damm and F. Krafft observed that rapid volatilization occurs in vacuo at 770° – 780° . A. Colson said that cadmium sulphide dissociates at 600° . A. Heiduschka stated that cadmium sulphide does not alter when cooled to -186° .

According to M. Berthelot,¹³ the heat of formation of zinc sulphide is (Zn, S) solid, 43.0 Cals., and, according to J. Thomsen, that of cadmium sulphide is 34.36 Cals. M. Berthelot also gave for one eq. of $\text{Zn}(\text{C}_2\text{H}_3\text{O}_2)_2$ in two litres of water and one eq. of H_2S in 10 litres of water, 1.81 Cals.; for dry $\text{Zn}(\text{C}_2\text{H}_3\text{O}_2)_2 + \text{H}_2\text{S}_{\text{gas}} = 2\text{HC}_2\text{H}_3\text{O}_{2\text{gas}} + \text{ZnS} + 3.0$ Cals.; $\text{ZnCl}_{2\text{soln.}} + \text{H}_2\text{S}_{\text{soln.}} = 2\text{HCl}_{\text{aq.}} + \text{ZnS} - 0.2$ Cal.; $\text{ZnSO}_{4\text{soln.}} + \text{H}_2\text{S}_{\text{soln.}} = \text{H}_2\text{SO}_{4\text{aq.}} + \text{ZnS} - 2.1$ Cals. According to J. Thomsen, the heat of the reaction between aq. soln. of zinc nitrate and hydrogen sulphide is -1.86 Cals., and for $\text{Cd} + \text{S} + n\text{H}_2\text{O} = \text{CdS} \cdot \text{H}_2\text{O} + (n-1)\text{H}_2\text{O} + 34.4$ Cals.

The **index of refraction** of yellow zinc blende from Picos de Europa (Santander, Spain) was found by A. des Cloiseaux¹⁴ to be $\mu = 2.341$ for Li-light, and $\mu = 2.369$ for Na-light, at 15° . W. Ramsay found $\mu = 2.34165$ for Li-light, $\mu = 2.36923$ for Na-light, and $\mu = 2.40069$ for Ti-light. E. T. Allen, J. L. Crenshaw, and H. E. Merwin found for pure sphalerite, $\mu = 2.3682$ for Na-light, and $\mu = 2.3983 \pm 0.0002$ for Ti-light; for wurtzite with the ordinary ray $\omega = 2.33$, and with the extraordinary ray $\epsilon = 2.35$; while the amorphous jelly may give $\mu = 2.18$ – 2.25 . The development of double refraction is the only conclusive evidence of the change from sphalerite to wurtzite by heat. The wurtzite begins developing at more than one point, and in different orientations, and the resulting structure is an intergrowth of lamellæ of wurtzite, and, as shown by P. Hautefeuille, each lamella has its principal axis parallel to one of the trigonal axes of the sphalerite grain. The double refraction of a grain thus transformed will be conditioned by the development of the four possible sets of lamellæ. J. Beckenkamp has considered that lamellæ of wurtzite may develop parallel to the trapezohedron of sphalerite. Such lamellæ would outcrop on a cleavage face parallel or normal to cleavages or bisecting the acute angle

between cleavage surfaces. All of the outcropping planes would be oblique to cleavage planes. E. T. Allen, J. L. Crenshaw, and H. E. Merwin observed no lamellæ of this kind. The refractive indices of greenockite were $\epsilon=2.447$ and $\omega=2.425$ for Li-light, and for Na-light $\epsilon=2.529$ and $\omega=2.506$. The refractive index of sphalerite is raised when ferrous sulphide is present, and that of greenockite artificially prepared is lowered by adsorbed impurities:

Per cent. FeS	. . . 0.2	8.6	17.0	28.2
Sp. gr. D	. . . 4.090	4.023	3.980	3.935
μ for Li-light	. . . 2.34	2.36	2.38	2.395
μ for Na-light	. . . 2.37	2.40	2.43	2.47
$(\mu-1)/D$ for Na-light	. . . 0.335	0.348	0.353	0.373

G. Horn, and W. Voigt gave for a pale yellow blende from Santander, and a black blende from St. Christoph (Breitenbrunn, Saxony), the refractive index μ , and the index of absorption, k :

		C-line.	D-line.	E-line.	F-line.	G-line.
Santander	μ	2.397	2.421	2.439	2.472	2.528
	k	0.0221	0.0194	0.0284	0.0265	0.0313
Breitenbrunn	μ	2.434	2.437	2.464	2.471	2.559
	k	0.0429	0.0529	0.0571	0.0623	0.0942

E. T. Allen, J. L. Crenshaw, and H. E. Merwin observed with a sample of sphalerite from Sonora (Mexico), and a sample of pure greenockite:

$\lambda=$	420	434	486	535	589	630	671	760 $\mu\mu$
$\mu=$	2.517	2.493	2.436	2.399	2.369	2.353	2.340	2.320

H. Becquerel and M. Baille made observations on this subject. S. y C. del Rio Calderon found for Na-light:

	20°	60°	100°	140°	180°	200°
μ	2.369	2.373	2.378	2.385	2.393	2.398

Wurtzite is optically positive; and the **double refraction** is feeble—this subject was investigated by A. des Cloizeaux, C. Friedel, J. L. C. Schröder van der Kolk, L. Bertrand, E. Mallard, J. Nöling, etc. W. Phillips, and A. Madelung found greenockite to be optically positive, and the double refraction feeble. D. Brewster showed that the crystals of zinc blende are optically anomalous, and the subject was investigated by P. Hautefeuille, J. Hirschwald, R. Brauns, E. Mallard, L. Bertrand, H. Rose, and F. Quiroga. For wurtzite, the double refraction $\epsilon-\omega$ is 0.019 for Li-light and 0.020 for Na-light; and for greenockite these values are respectively 0.025 and 0.023. The curves for the variation of the refractive index of greenockite with the wave-length gradually approach one another since the refractive index ω increases more rapidly than ϵ ; there is therefore a change in the optical sign at the point of intersection of the curves when $\mu=2.6$ and $\lambda=525\mu\mu$ (extrapolation). The light absorption of greenockite was found by E. T. Allen, J. L. Crenshaw, and H. E. Merwin to be very small for ω below a wave-length $519\mu\mu$, and from 517 to $511\mu\mu$ it increases to near complete opacity; for ϵ , absorption begins near $512\mu\mu$, and increases to $506\mu\mu$. W. W. Coblentz measured the **infra-red transmission spectrum** for sphalerite and found the crystals to be transparent from 5 to 12μ , with slight depressions in the curve at 1.6, 11.2, and 13.2μ ; there is a wide band from 2.7 to 3.3μ , and complete opacity beyond 15μ . The **infra-red reflection spectrum** was also studied by W. W. Coblentz, and by T. Liebisch and H. Rubens.

E. L. Nichols and D. T. Wilbur¹⁵ found that purified zinc sulphide, like calcium oxide, exhibits **flame luminescence**. Highly purified zinc sulphide—wurtzite or sphalerite—either shows no **phosphorescence** or it phosphoresces very slightly. E. MacDougall, A. W. Stewart, and R. Wright showed that highly purified zinc sulphide can be obtained in a condition which enables it to phosphoresce; the amorphous sulphide does not phosphoresce, nor does the wholly crystalline sulphide phosphoresce so well as a semi-crystalline sulphide. The fused sulphide was found

by E. Tiede and A. Schleede to be strongly phosphorescent. The temp. to which the zinc sulphide has been heated and the time of heating have the greatest influence on the phosphorescence. W. Molthan found the dielectric constant is increased in light. According to E. Tiede and A. Schleede, the effect of a flux in inducing the phosphorescence of zinc sulphide is not due to the formation of a definite crystalline form, but rather to the lowering of the m.p. The presence of certain impurities—*e.g.* iron—inhibits the phosphorescence; others—*e.g.* manganese—alter the tint. The presence of a chloride favours the phosphorescence, so that, as E. MacDougall and co-workers showed, samples of the sulphide made from zinc salts not containing chlorides do not phosphoresce so brilliantly as those produced in the presence of chlorides; presumably some chloride is adsorbed as an impurity not removable by washing—*vide* the phosphorescence of the sulphides of the alkaline earths. As a rule, natural zinc blende does not phosphoresce. When the isolated mineral is examined in a darkened room, S. R. Mourelou found the phosphorescence is more intense with diffused daylight than with sunlight; W. Trenkle found the **photoluminescence** to be favoured by concentrating the rays from an arc-light with a lens. K. A. Hofmann and W. Ducca found that the luminescence is evoked by exposure to daylight, the incandescent light, arc-light, Becquerel's rays, and cathode rays, and H. Zahn, B. Gudden and R. Pohl, that the phosphorescence can be excited in powerful electric fields—say 3000 volts per cm. M. Curie studied the effect of the red and infra-red rays on phosphorescent zinc sulphide. He observed that the sulphur atoms of the X-radiogram were not influenced—it was assumed that if these atoms were agitated by light, there would be a diminished intensity in the reflected X-rays. J. L. Pech found samples of zinc sulphide which phosphoresced in the ultra-violet, but not in the infra-red; and L. B. Löb and L. Schmiedeskamp noted a decrease in the intensity of the phosphorescence as the time of exposure to ultra-violet light increased. W. Crookes, H. Becquerel, T. Tommasina, P. Curie and A. Debiere, H. Grüne, and A. A. Guntz studied the phosphorescence which zinc blende produces when exposed to radium radiations. The phosphorescence is also evoked by exposure to the spark discharge; the X-rays and the canal rays are also effective. According to H. A. Bumstead, the scintillations of zinc blende are produced by the secondary rays from lead. According to H. Becquerel and T. Tommasina, the α -rays produce a scintillating phosphorescence which rapidly vanishes. According to J. Elster and H. Geitel, the phenomenon is produced by the radioactive emanation from the earth, and by air which has been passed over thorium hydroxide. According to H. Becquerel, the scintillation is not produced by ionization, but by the impact of the α -particles of radium, and is obtained by rubbing zinc blende between two glass plates, *i.e.* the flash is due to the cleavage of the crystals by the bombardment with α -corpuscles, *i.e.* of triboluminescence. W. Crookes also regarded the flash as an effect of the impact of an α -particle. R. W. Wood found the duration of the flash is between 15×10^{-5} and 20×10^{-5} secs. and is shorter than the triboluminescent flash so that the two phenomena are not closely related. Only a small percentage of the sulphide phosphoresces under the α -rays. He assumes that the flash occurs only when an electron strikes a molecule of the impurity because the number of α -particles emitted by radium far exceeds the number of flashes in the spinthariscopes. E. Wiedemann and G. C. Schmidt assume that the active substance is dissociated during excitation, and that the recombination of the products of dissociation is accompanied by the emission of light. Mixtures of radium with zinc sulphide emit a greenish-yellow light due to the bombardment of the zinc sulphide crystals by the α -particles from the radium. The mixture has been used for permanently illuminating keyholes, the hands of clocks and watches, etc., so that these may be readily seen in the dark. C. Henry found phosphorescent zinc sulphide enhances the photographic activity of X-rays. H. Herszfeld and L. Wertenstein have shown that the range of the α -particles in zinc sulphide is of the order of some hundredths of a millimetre. R. Pohl and co-workers studied the dielectric constant of phosphorescent zinc sulphide.

F. Giesel and J. Zanneck found the phosphorescence of Sidot's blende exceeds that of all other known substances. According to C. Baskerville and L. B. Lockhart, Sidot's blende phosphoresces under the influence of the gaseous emanations obtained when some rare-earth minerals are heated, but purified preparations of uranium or thorium give no results. According to A. S. Eakle and W. T. Sharwood, zinc blendes from Kapnik (Hungary), Mariposa (California), Eureka (Nevada), Utegrube (Rico), etc., are phosphorescent. These blendes lose the quality superficially when heated to 1000° , and when roasted, this property is destroyed. Artificial or natural zinc blende which has been heated in a stream of hydrogen acquires the property of phosphorescing, and A. Verneuil suggests that hydrogen possibly produces a lower zinc sulphide which is the cause of the phenomenon.

T. L. Phipson observed that a white pigment prepared by precipitating zinc sulphide from a soln. of zinc sulphate by barium sulphide, appeared black all day, and again became white at night. The powder exposed to sunlight became fawn-coloured, brown, and finally a dark slate colour in about 20 mins. If the darkened powder be placed in darkness, it becomes white again in $2\frac{1}{2}$ to 3 hrs. The power of alternately darkening and whitening was lost in a few days, although specimens of the powder have retained the property for months or years. T. L. Phipson wrongly assumed that the blackening is due to the presence of an element sensitive to light and which he called *actinium*. J. Cawley assumed that some zinc oxide is formed during the calcination, and that this reacts with zinc sulphide, forming zinc and sulphur dioxide which blackens the mass. This agrees with the fact that (i) the sensitiveness to light is greater when the sulphide is moist than when it is dry, and (ii) the presence of magnesia retards the blackening.

Zinc sulphide is sometimes substituted for zinc-white as a pigment, and it has rather a greater covering power. The sulphide is made by bringing together the vapours of the two elements, and collecting the product in settling chambers from which air is excluded. J. Cawley, and C. Clerc and A. Nihoul also described manufacturing processes. As a rule, the sulphide is not used alone, but is mixed with barium sulphate—C. F. Claus. Hot soln. of barium sulphide and zinc sulphate are mixed, and the washed precipitate is dried, mixed with ammonium chloride, heated to redness, and quenched in water. The product is used as a pigment under the trade name *lithophone*. An analogous mixture of zinc sulphide and calcium sulphate furnishes *sulphophone*—C. R. P. Steinau. Lithophone turns grey in direct sunlight. If mixed with lead or copper compounds, the paint blackens owing to the formation of black lead or copper sulphide. Zinc sulphide and lithophone are coloured grey by exposure to light or by heating them to 60° – 70° . W. J. O'Brien attributed the coloration to the decomposition of the sulphide into sulphur and metal, but Y. Nishizawa could detect no free sulphur in a discoloured specimen, and he attributes the coloration to the polymerization of the sulphide. He found the discoloration is promoted by magnesium, zinc, or calcium chloride or sulphate; and inhibited by polyhydric alcohols, sugars, starch, oxalic acid, tartrates, etc.

From the discussion on the preparation it follows that the phosphorescence of zinc sulphide is dependent on the presence of small traces of certain impurities. According to A. Verneuil, and P. Lenard and V. Klatt, the presence of 0.001 part of zinc sulphide changes the colour but not the intensity of the phosphorescence of calcium sulphide. C. A. Pierce studied the decrease in phosphorescence produced at temp. rising from 15° to 300° . E. Wiedemann and G. C. Schmidt say that the phosphorescence of Sidot's blende is retained up to 500° , and the glow is gradually extinguished. C. Henry found the rate of decay of the phosphorescence could be represented by the rule $I = I_0 e^{-at}$, where the intensity of the light at the time t is represented by I ; and I_0 is the initial intensity; a and e are constants. E. Becquerel gave the more complex formula $I^{0.5936}(27.18+t) = 1647.5$. R. Tomaschek examined the effect of different modes of preparation on the spectrum of the phosphorescent light.

L. Clémandot found that the phosphorescence of zinc blende is excited mainly by the rays more refrangible than the *F*-ray. A. Dahms showed that an exposure to the ultra-red rays rapidly extinguishes the phosphorescence of zinc blende. R. Danneberg found that wurtzite phosphoresces with light of short wave-length

and the luminosity is extinguished by heat rays. The photoluminescence decays more slowly than the cathodoluminescence. The phosphorescence is most intense when evoked by exposure to the violet and blue rays; the green rays produce a feeble phosphorescence; and the rays from orange to red produce no result. According to E. L. Nichols and E. Merritt, the luminescence spectrum shows two well-defined bands at $\lambda=0.507\mu$ and $\lambda=0.432\mu$; the violet band is produced by the ultra-violet part of the arc-light between iron or zinc electrodes; the green band is most rapidly produced by the violet band of the arc between carbon electrodes; and both bands are produced by X-rays, and by ultra-violet light. The phosphorescence of Sidot's blende does not follow Stokes' law. The full effect of the exciting light is produced in three seconds. The intense violet light is of short duration and dies out in one or two tenths of a second; while the fainter green light is of long duration, and it can be detected several hours after excitation has ceased. E. Lenard said that the blackening which occurs when zinc sulphide is exposed to light is due to a film of finely divided zinc; the blackening does not occur in the absence of moisture.

According to W. Trenkle, zinc blende exhibits **triboluminescence** when triturated, compressed, or hammered. According to W. S. Andrews, zinc sulphide prepared in the following manner emits sparks of yellow light when scratched with a knife:

Triturate a mixture of 70 parts of zinc carbonate with 30 of flowers of sulphur to a thick cream with distilled water in which a little manganese sulphate has been dissolved. Dry the mass at a gentle heat, and pack the powder in a porcelain or plumbago crucible and heat to bright redness for 20 mins.

The sparks do not ignite inflammable vapours. A. A. Guntz made some observations on this subject. The phenomenon was first reported by F. Hofmann in 1750, the effect may be really **thermoluminescence** due to the heat developed by friction. The thermoluminescence is brilliant but rapidly decays. According to A. S. Eakle and W. T. Sharwood, zinc blende from Mariposa (California) exhibits a strong triboluminescence, and the ore is a mixture of barytes, and zinc blende with sulphides of lead, antimony, and copper. E. Wiedemann and G. S. Schmidt found many mixtures of salts are triboluminescent—*e.g.* isomorphous mixtures of zinc sulphide with the sulphides of the alkaline earths. H. Grüne refers the triboluminescence of natural blende to the presence of traces of manganese. According to H. Baumhauer, Sidot's blende luminesces if breathed upon, if exposed to steam, or if treated with cold or hot water; and M. Seddig found that it luminesces when cooled. According to R. Schenck and F. Mihr, Sidot's blende begins to luminesce when exposed to ozonized air, and F. Richerz and R. Schenck say that this is not due to oxidation. L. Vanino found that a photographic plate wrapped in paper is blackened by zinc sulphide in consequence of the reducing action of hydrogen-sulphide vapour—if surrounded by celluloid, transparent to Becquerel's rays, the blackening does not occur.

B. Pelletier¹⁶ found zinc sulphide to be a good conductor of electricity, but, added M. Kiliani, only when the sulphide is impure. F. Beijerinck found the **electrical conductivity** even of the dark varieties of zinc blende is nil; wurtzite and greenockite conduct feebly at ordinary temp., but the conductivity increases as the temp. is raised—the conductivity, according to M. Kiliani, is due to polarization currents and infra-crystalline separations of zinc. G. Karsten found that cadmium sulphide prepared in the dry way conducts electricity feebly, but if prepared in the wet way, it is a non-conductor. F. Beijerinck found yellow greenockite is a non-conductor, while the orange sulphide is a conductor. R. Bädecker studied the conductivity of thin films of cadmium sulphide. G. Tammann measured the potential of zinc blende against the normal hydrogen electrode, and showed that in aq. soln. there is an exchange of ions. B. Gudden and R. Pohl found that the electrical conductivity of zinc and cadmium sulphides is augmented in light. H. Zahn measured the rectifying effect of zinc blende on alternating currents. Crystals of

zinc blende were found by C. Friedel and P. Curie to exhibit **pyroelectricity** such that the tetrahedral surface and the corners were oppositely charged; J. and P. Curie observed that the crystals exhibited **piezoelectricity** where the tetrahedral surfaces were negatively charged, and the corners were positively charged. W. Schmidt found the **dielectric constant** of zinc blende to be 75; and the electrical index of refraction 7.85. B. Gudden and R. Pohl observed that the dielectric constant is increased under the influence of light; and that the increase with monochromatic light is less rapid than the increase in the intensity of light. According to P. Curie, zinc blende is a dielectric to which the law of the superposition of e.m.f. does not apply, probably because of liquid inclusions. H. Becquerel said that the **magnetic rotation** of the plane of polarization of zinc blende is seventeen times the value for water. W. Voigt and S. Kinoshita measured the **magnetic susceptibility** of zinc blende. O. Knoblauch, and B. Gudden and R. Pohl showed that zinc blende, greenockite, or cadmium sulphide exhibit the **photoelectric effect**. W. Biltz found that colloidal zinc or cadmium sulphide suspended in water, under the influence of an electric current, migrated to the cathode. The coagulation of colloidal cadmium or zinc sulphide in sunlight was observed by P. B. Ganguly and N. R. Dhar.

The chemical properties of zinc and cadmium sulphides.—According to K. Hüttner,¹⁷ a specimen of zinc blende at 800° to 850° gave off 1.6 times its vol. of **occluded gases**—hydrogen, 14.6 per cent.; carbon monoxide, 75.6 per cent.; and nitrogen, 9.8 per cent., but no rare gases. According to A. Mourlot, zinc sulphide is not decomposed when heated even in the electric-arc furnace provided air be absent; and W. Fränkel observed no change when zinc blende is heated to 1300° in an atm. of **nitrogen**. H. St. C. Deville and L. Troost, H. N. Morse and J. White, and A. Verneuil found that zinc or cadmium sulphide sublimes when heated in a stream of **hydrogen**. P. Berthier found that hydrogen has no action on zinc sulphide. E. Pollacci regarded zinc sulphide as a member of those sulphides difficult to oxidize in **air**. Cadmium sulphide is moderately oxidizable in air; F. Janda said that zinc blende oxidizes in air faster than galena; and A. Kunze and K. Danziger, that it oxidizes in moist air between 50° and 300° more slowly than iron pyrites. R. Wagner found that zinc blende slowly decomposes in moist air with the evolution of hydrogen sulphide, and J. Böhm stated that it gives off hydrogen sulphide between 150° and 200°. A. Richardson found that cadmium yellow becomes paler when exposed to light in moist air owing to its oxidation to the sulphate, but in dry air it is not changed.

When zinc sulphide is heated to redness in air, zinc oxide and zinc sulphate are formed. The roasting proceeds with difficulty, and, as F. Janda, J. Sachse and E. Richter, and L. Bemelmans have shown, the powder to be roasted should be in a finely divided state. The roasting of zinc sulphide in an atm. of **oxygen** proceeds: $2\text{ZnS} + 3\text{O}_2 \rightarrow 2\text{ZnO} + 2\text{SO}_2$; the reverse reaction has not been observed. There is an unstable equilibrium between sulphur dioxide and oxygen in the presence of the catalytic agents: $\text{SO}_2 + \text{O}_2 \rightleftharpoons 2\text{SO}_3$; and the sulphur trioxide reacts with the oxide: $\text{ZnO} + \text{SO}_3 \rightleftharpoons \text{ZnSO}_4$. There is then a definite press. of sulphur trioxide corresponding with every temp.—*vide* sulphur trioxide. L. and P. Wöhler and W. Plüddemann give for the dissociation press. of zinc sulphate in mm. of mercury:

Press.	675°	690°	720°	750°	775°	800°
	5	6	24	61	112	189

When the temp. of the roasting sulphide rises to bright redness, the sulphate is decomposed; according to H. O. Hofman, a basic sulphate is formed, and at a white heat zinc oxide results. K. Friedrich found that sulphur dioxide can be detected at 40°, and the sulphide begins to glow in oxygen at 662° to 775°. J. W. Richards has calculated a theoretical temp. from the heats of formation of the reacting substances. R. Hasenclever showed that the best temp. for roasting zinc sulphide is about 960°, and the resulting zinc oxide should not be exposed to the action of carbon monoxide, or losses will occur through the reduction and volatilization of

zinc. E. Jensch found about two per cent. of sulphide-sulphur remained in roasted blende, and E. Orgler stated that well-roasted blende should not contain over 0.25 per cent. of sulphide-sulphur. V. Lepiarczyk converted pure zinc sulphide wholly into the oxide by roasting, but with blende containing lime, calcium sulphate was formed. F. Kellermann, E. Prost, F. A. Thum, C. Ritter, E. Schuchard, E. Schütz, C. F. Plattner, F. Janda, A. Voigt, H. Brandhorst, H. Pommerenke, and P. Truchot, have studied the roasting of blende. H. O. Hofman found ferruginous blendes more difficult to roast than blendes containing less iron, and the yield of sulphate is higher; he did not find it possible to convert more than 9 per cent. of a raw blende into sulphate by roasting. E. Prost and E. Lecocq studied the roasting of fluoriferous blendes; C. Sander, argentiferous blendes; W. Mostowitsch, and C. Sander, barytiferous blendes; and G. Waring, J. E. Williams, E. Orgler, and V. Lindt, calcareous blendes. J. C. Clancy and L. W. Marsland shortened the time of roasting by mixing the blende with lead sulphate. A. Helbronner and W. Rudolfs state that certain bacteria, described by J. G. Lipman and co-workers, have been found which are capable of converting blende into zinc sulphate, and that the solubility of the product does not prevent the further action of the bacteria. The oxidation is favoured by the presence of sulphur, and under such conditions the bacteria can convert the native silicate and carbonate into sulphate. If lead sulphide is present, only the zinc sulphide is attacked, and the two metals can thus be separated.

According to A. Mailfert,¹⁸ **ozone** converts zinc or cadmium sulphide into the sulphate. When zinc sulphide is heated in **water** vapour, H. V. Regnault found that zinc oxide and hydrogen sulphide are formed, the decomposition is incomplete except at a very high temp. in a porcelain tube, and the zinc oxide is then deposited in small silky masses in that part of the tube from which the steam escaped; similar remarks apply to cadmium sulphide. From the electrical conductivity determinations, O. Weigel found for the solubility of zinc blende from Santander, 6.65×10^{-6} mol per litre; for artificial crystals, 5.0×10^{-6} and 8.0×10^{-6} mol per litre; for wurtzite, 28.82×10^{-6} mol per litre; for greenockite, 8.99×10^{-6} mol per litre; and for precipitated zinc and cadmium sulphides, respectively 70.60×10^{-6} and 9.00×10^{-6} mol per litre; L. Bruner and J. Zawadsky, 5.0×10^{-26} or 8.0×10^{-26} mol per litre for the alleged α -ZnS, and 1.1×10^{-24} mol per litre for β -ZnS. W. Biltz found from ultra-microscopic observations that the solubility of cadmium sulphide is 6.6×10^{-6} mol per litre at 16° to 18° .

Cold **chlorine** gas, or chlorine water, has very little action on zinc sulphide, but above 30° zinc and sulphur chlorides are formed: $2\text{ZnS} + 3\text{Cl}_2 = 2\text{ZnCl}_2 + \text{S}_2\text{Cl}_2$; W. Borchers and A. Dorsemagen¹⁹ stated that the action begins in the wet way at 30° – 40° with the liberation of sulphur, and E. A. Ashcroft said the reaction begins above 600° : $\text{ZnS} + \text{Cl}_2 = \text{ZnCl}_2 + \text{S}$. E. Schäfer observed no reaction when zinc blende is heated to dull redness with chlorine or **bromine**. E. Filhol and J. Melliès found that when heated with **iodine** in a sealed tube at 200° , zinc sulphide is completely transformed into zinc iodide. H. V. Regnault found zinc blende to be soluble in hot conc. **hydrochloric acid**, with the evolution of hydrogen sulphide—*vide supra*, preparation of zinc sulphide. F. Stromeyer found that cadmium sulphide is sparingly soluble in hot dil. hydrochloric acid, but easily soluble in cold conc. acid; O. Follenius and W. Spring made a similar observation. J. B. Meyer converted the sulphide into chloride by heating it in a stream of hydrogen chloride. L. E. Rivot, F. S. Beudant, and P. A. Daguin found that powdered zinc sulphide is completely dissolved when digested for some hours with a hot conc. soln. of potassium hydroxide sat. with chlorine—**alkali hypochlorite**; S. S. Sadtler also found it to be dissolved by an alkaline soln. of sodium hypochlorite; and J. Lemberg by an **alkali hypobromite** soln. F. Repiton found zinc sulphide decomposes **starch iodide**. A. S. Cushman found that unlike copper sulphide cadmium sulphide is soluble in a hydrochloric acid soln. of **sodium chloride**. The chloridized roasting of pure blende has been previously discussed.

According to F. Wöhler and co-workers,²⁰ **sulphur dioxide** reacts very slowly with zinc blende, forming sulphur $2\text{ZnS} + \text{SO}_2 = 2\text{ZnO} + 3\text{S}$; the film of basic sulphide simultaneously formed protects the sulphide from the sulphur dioxide. Zinc blende was found by E. F. Smith to be completely decomposed by the vapour of **sulphur chloride**, S_2Cl_2 ; and N. A. Orloff, and H. Feigl found that when dry zinc or cadmium sulphide is shaken with a benzene soln. of sulphur chloride, S_2Cl_2 , and the liquid decanted from the greenish-black lumps, and warmed to 70° , almost pure sulphur is deposited. They also found that similar results are obtained by digesting dry cadmium sulphide with benzene, carbon disulphide, or toluene soln. of sulphur chloride. E. Paterno and A. Mazzuchelli found that **sulphur bromide**, S_2Br_2 , acts similarly, while the so-called **sulphur iodide**, S_2I_2 , is inactive. H. St. C. Deville and L. Troost found that zinc sulphide does not sublime in a stream of **hydrogen sulphide**. According to A. Villiers, amorphous zinc sulphide dissolves in an aq. soln. of hydrogen sulphide, but the crystalline sulphide does not dissolve in that menstruum. G. F. Becker found that zinc sulphide is soluble in a cold soln. of **sodium sulphide**, Na_2S , without the development of gas; almost insoluble in a cold, but a little more soluble in a hot soln. of **sodium hydrosulphide**, NaSH ; and soluble in a soln. of sodium carbonate partially sat. with hydrogen sulphide. P. Berthier stated that zinc sulphide combines with most of the metal sulphides—iron, antimony, lead—though with difficulty, and the combinations which are formed do not readily fuse. L. L. de Koninck could find no evidence of a compound of zinc and ferrous sulphides. R. Schindler prepared **potassium zinc sulphide**, $\text{K}_2\text{S} \cdot 3\text{ZnS}$, or $\text{K}_2\text{Zn}_3\text{S}_4$, by dissolving zinc sulphide in a molten mixture of sulphur and potassium carbonate and, after 10 mins.' fusion, washing the cold mass with water. The small colourless crystals are stable in air; and they are not changed when heated red hot in the absence of air, or hydrogen. They do not give potassium sulphide with hot or cold water, but the moist crystals exposed to air, slowly form potassium thiosulphate. They are readily decomposed by mineral acids; with silver nitrate, they form **silver zinc sulphide**, $3\text{ZnS} \cdot \text{Ag}_2\text{S}$; and with cupric sulphate, they form **cupric zinc sulphide**, $\text{CuS} \cdot 3\text{ZnS}$; but they do not react with mercuric chloride, lead nitrate, or thallium sulphate. Mixtures of zinc sulphide and **cuprous sulphide** do not show any eutectic structure, and only a single branch of the f.p. curve could be observed, the eutectic point, if present, lying close to the f.p. of cuprous sulphide. Mixtures of the **sulphide of silver** and that of zinc form a eutectic containing 3 per cent. ZnS and solidifying at 800° . R. Schindler also made **sodium zinc sulphide**, $\text{Na}_2\text{S} \cdot 3\text{ZnS}$, in an analogous manner. J. Milbauer prepared a **potassium cadmium sulphide** by melting cadmium oxide with potassium thiosulphate; but not the corresponding **sodium cadmium sulphide**, although R. Schneider prepared the latter by fusing cadmium sulphide with sodium carbonate and sulphur; the yellow crystalline powder remaining after washing with dil. alcohol had the composition $\text{Na}_2\text{Cd}_3\text{S}_4$, or $\text{Na}_2\text{S} \cdot 3\text{CdS}$.

A. Gueront found that zinc or cadmium sulphide is slightly soluble in an aq. soln. of **sulphur dioxide**, forming a thiosulphate; P. Berthier found freshly precipitated zinc sulphide dissolves in sulphurous acid. A. Rosentiehl noted that zinc chloride is formed when sulphur dioxide is passed into dil. hydrochloric acid holding zinc sulphide in suspension. According to H. V. Regnault, and M. Berthelot, zinc sulphide is largely decomposed by evaporation with conc. **sulphuric acid**. S. Glaxelli found that the so-called β - ZnS is 4.6 times as soluble as α - ZnS in dil. sulphuric acid; he also found at 25° with $N\text{-H}_2\text{SO}_4$, 10 c.c. of a soln. of zinc blende from Santander contained 0.00059 grm. of zinc; with α - ZnS , precipitated at ordinary temp. the soln. contained 0.0025 grm. Zn; and when precipitated at 0° , 0.018 grm. Zn; the soln. of β - ZnS , precipitated at ordinary temp., contained 0.010 grm. Zn; and precipitated at 0° , 0.0316 grm. Zn when the sulphide was fresh, and 0.016 grm. of Zn when 5 days old—*vide supra*, preparation of zinc sulphide. A. W. Hofmann stated that cadmium sulphide is soluble in boiling $\frac{1}{3}N\text{-H}_2\text{SO}_4$, and O. Follenius, in boiling dil. sulphuric acid. R. Meldrum stated that cadmium sulphide is insoluble

in sulphuric acid. According to E. Jannettaz, when heated with **potassium hydrosulphate**, KHSO_4 , zinc blende gives a little hydrogen sulphide.

H. W. F. Wackenroder²¹ stated that cadmium sulphide is very sparingly soluble in aq. **ammonia**. H. Brandhorst found zinc blende is soluble in a boiling soln. of **ammonium acetate** with the separation of sulphur. C. R. Fresenius, and A. Ditte found **ammonium sulphide** dissolves marked quantities of cadmium sulphide, and a soln. of an **alkali sulphide** dissolves less, but E. Donath and J. Mayrhofer, and C. R. Fresenius added that the solubility is so small as to be of negligible importance in analysis. G. P. Baxter and M. A. Hines found cadmium sulphide to be appreciably soluble in a soln. of **ammonium chloride**, and P. de Clermont found both cadmium and zinc sulphides to be soluble in a boiling soln. of ammonium chloride. Zinc sulphide is soluble in weak mineral acids, best in **nitric acid**. H. V. Regnault, for example, stated that it dissolves in nitric acid with the separation of sulphur. W. Meissner, and O. Follenius, found cadmium sulphide to be readily soluble in nitric acid. J. Percy found that zinc sulphide is energetically oxidized when heated with an **alkali nitrate**, forming zinc oxide and alkali sulphate.

According to J. Percy,²² and P. Berthier, when zinc sulphide is heated with **carbon**, or in a carbon-lined crucible, it volatilizes completely, leaving behind ferrous sulphide, if it contains iron; he added that the zinc sulphide is probably decomposed with the formation of carbon disulphide. According to F. Janda, zinc sulphide is reduced with great difficulty by carbon. H. Moissan found that zinc sulphide is reduced by carbon in the electric arc furnace. W. Fränkel heated zinc blende mixed with 10 per cent. of carbon in a porcelain boat in a quartz tube; between 1300° and 1350° , the porcelain and quartz were attacked, and the composition of the condensate was **zinc thiosilicate**, ZnSSi , with traces of carbon disulphide in the evolved gases. V. Lindt, and V. Lepiarczyk concluded that the reaction between carbon and zinc sulphide is to be symbolized: $2\text{ZnS} + \text{C} = 2\text{Zn} + \text{CS}_2$. This reaction between carbon and the metal sulphides was indicated by C. Stölzel in 1863. When zinc sulphide is heated with carbon and lime, metallic zinc and calcium sulphide are formed; the reaction is incomplete and depends on the temp. J. Percy found that zinc sulphide, even at a red heat, is not affected by dry **carbon dioxide**. N. D. Costeanu observed no action at 600° , but at 750° there are indications of a reaction: $\text{ZnS} + \text{CO}_2 = \text{CO} + \text{ZnO} + \text{S}$; with cadmium sulphide dissociation begins at about 600° , but the gas exerts no chemical action. According to P. Berthier, when zinc sulphide is fused with **alkali carbonates** at a red heat, a mixture of zinc oxide, zinc sulphate, and alkaline sulphide is formed. Freshly precipitated zinc sulphide was found by H. W. F. Wackenroder to be slightly soluble in a large excess of **acetic acid**; and R. Meldrum said that cadmium sulphide is insoluble in acetic acid. W. Fränkel found that when zinc sulphide is mixed with **silicon**, and heated in a quartz boat in a quartz tube, distillation begins at 1150° , and ZnSSi is formed as in the case of carbon in the porcelain boat. O. Stutzer has studied the action of zinc blende on natural **silicates**.

According to J. Percy,²³ **iron** decomposes zinc sulphide at a bright red heat, forming ferrous sulphide and the vapour of zinc; C. A. Graumann found the reaction with finely divided iron: $\text{ZnS} + \text{Fe} = \text{FeS} + \text{Zn}$, is practically complete at 1300° . J. Percy continued: the reduction with **tin** is more or less incomplete; **antimony** does not reduce zinc sulphide even at a high temp.; **lead** reduces zinc sulphide very imperfectly; and **copper** reduces zinc sulphide at a high temp., forming a regulus, and the proportion of zinc remaining alloyed with the copper depends on the temp. and the duration of the operation.

E. F. Smith found that powdered zinc blende is oxidized when suspended in molten **potassium hydroxide** with the containing nickel dish as anode. Cadmium sulphide, said C. R. Fresenius, is quite insoluble in alkali lye. S. H. Walton and H. A. Scholz found that **sodium peroxide** with a trace of potassium persulphate is a convenient medium for opening up zinc blende for analysis. According to P. Berthier, zinc sulphide and **calcium oxide** decompose one another only in the

presence of carbon ; but J. Percy obtained some decomposition when lime and zinc sulphide were heated together ; and E. Prost found that eq. quantities of lime and zinc sulphide react at 1200° , but with 75 per cent. excess of lime, decomposition is complete at 1250° . P. Berthier stated that zinc oxide does not decompose zinc sulphide, but the two components form a **zinc oxysulphide** which is fusible at high temp. C. Kersten reported a crystalline incrustation, $\text{ZnO} \cdot 4\text{ZnS}$, on a Freiburg furnace, but J. J. Berzelius pointed out that the analysis of C. Kersten did not justify the proposed formula. The mineral *voltzite* examined by A. Breithaupt, J. Fournet, J. F. Vogl, etc., has a similar formula. F. Beijerinck regards *voltzite* as an isomorphous mixture of wurtzite and zincite. C. F. Rammelsberg, and J. A. Arfvedson obtained what they regarded as zinc oxysulphide, $\text{ZnO} \cdot \text{ZnS}$, by calcining zinc sulphate in a stream of hydrogen. The product was probably a mixture of oxide and sulphide. From J. Percy's experiments **copper oxide** and zinc sulphide appear to decompose each other, forming a button of metal and a regulus. P. Berthier found that with **lead oxide**, sulphur dioxide, lead, and zinc oxide are produced. P. Berthier found that at a white heat, **manganese dioxide** and zinc sulphide furnish sulphur dioxide, zinc oxide, and manganous oxide. V. Lindt, and V. Lepiarczyk found **ferric oxide** reacts quantitatively with zinc sulphide at 1300° in the absence of air, probably $2\text{Fe}_2\text{O}_3 + 4\text{ZnS} = 4\text{FeO} + \text{Zn} + 3\text{ZnS} + \text{SO}_2 = 3\text{FeS} + \text{Fe} + 4\text{ZnO} + \text{SO}_2$; and if carbon is also present, $\text{Fe}_2\text{O}_3 + 2\text{ZnS} + 4\text{C} = 2\text{Fe} + 2\text{Zn} + 3\text{CO} + \text{CS}_2$. It is possible that the ferric oxide is first reduced by carbon to ferrous oxide and iron, which then react with the zinc sulphide.

J. Lemberg²⁴ found that an acid soln. of **silver sulphate** reacts with zinc sulphide, forming silver sulphide ; F. Raschig observed that a boiling soln. of **cupric chloride** converts zinc blende into zinc chloride, and cupric sulphide ; and zinc blende with a soln. of **cuprous chloride** in sodium chloride is incompletely converted into zinc chloride and cuprous sulphide. E. Schürmann found precipitated zinc sulphide, at 100° , reacts completely with soln. of cupric sulphate, **cadmium sulphate**, **stannous chloride**, and **lead nitrate**, but not with soln. of **ferrous sulphate** or **thallium nitrate** ; he also found that cadmium sulphide is completely decomposed by a soln. of cupric sulphate, partially with stannous chloride, and not with **lead acetate**, **zinc sulphate**, **nickel sulphate**, or **tartar emetic**. Hot soln. of **ferric chloride** were found by H. Brandhorst to be reduced by zinc sulphide ; G. de Bechi and R. W. Rücker found that zinc sulphide is soluble in **ferric sulphate** soln. and the latter are reduced ; and J. Perino found that with **ferric nitrate** at 150° to 200° , zinc sulphide is oxidized before ferrous sulphide. According to E. A. Parnell, when an intimate mixture of **zinc sulphate** and sulphide is heated, zinc oxide and sulphur dioxide are formed : $\text{ZnS} + 3\text{ZnSO}_4 = 4\text{ZnO} + 4\text{SO}_2$.

R. Meldrum²⁵ prepared **colloidal cadmium sulphide** by the action of hydrogen sulphide on a dil. soln.—containing say 0.015 per cent. of cadmium sulphide ; W. Biltz also made colloidal zinc and cadmium sulphides. **Colloidal zinc sulphide** can be prepared in a similar way. As shown by P. Donnini, and J. Hausmann, the ordinary amorphous precipitate forms a colloidal soln. as the adsorbed salts are removed by washing. C. Winssinger obtained colloidal zinc sulphide by passing hydrogen sulphide into water with zinc hydroxide, or ordinary precipitated zinc sulphide in suspension. J. Thomsen obtained the pale opalescent soln. by the action of an alkali hydrosulphide on a dil. soln. of zinc sulphate. V. von Zotta, and L. W. McCay used a similar process. L. Vanino and F. Hartl prepared a gold-yellow clear colloidal cadmium sulphide by treating with hydrogen sulphide a soln. of 0.2 gm. of cadmium sulphate in a litre of water. E. Prost precipitated cadmium sulphide by treating an ammoniacal soln. of cadmium sulphate with hydrogen sulphide, and, suspending the well-washed precipitate in water, treated it anew with hydrogen sulphide. According to J. Hausmann, if a soln. of sodium sulphide in 5 per cent. gelatine, agar-agar, or starch be brought in contact with a dil. aq. soln. of cadmium salt, so that the one soln. can diffuse with the other, a golden-yellow layer of the colloid is formed. Colourless or yellow **ammonium sulphide** does not work.

A. Müller obtained colloidal zinc sulphide by allowing a mixture of zinc sulphate and glycerol to stand in contact with ammonium sulphide for three days.

Freshly precipitated zinc or cadmium sulphide is often colloidal and contains adsorbed water; and it then dissolves in acids more readily than the dried sulphide. H. Reinsch found the coagulum retains some chloride when precipitated from soln. of zinc chloride. A sample of precipitated zinc sulphide dried at 100° was found by P. L. Geiger and K. L. Reimann, and H. W. F. Wackenroder to have the composition $2\text{ZnS} + \text{H}_2\text{O}$; H. W. F. Wackenroder, R. Wagner, and A. Souchay found samples dried at 100° had the composition $3\text{ZnS} + \text{H}_2\text{O}$; P. L. Geiger and K. L. Reimann, and A. Souchay, the composition $4\text{ZnS} + \text{H}_2\text{O}$; and by the action of hydrogen sulphide in air-dried zinc hydroxide, $\text{ZnS} + n\text{H}_2\text{O}$. R. Schindler obtained crystalline plates of a hydrate by the action of a very slow current of hydrogen sulphide on a soln. of zinc sulphate. When dried at 37.5° , the composition was $\text{ZnS} + \text{H}_2\text{O}$. S. E. Linder and H. Picton found the composition of the air-dried precipitate corresponded with $3\text{ZnS} \cdot 2\text{H}_2\text{O}$. For the heat of hydration of zinc sulphide, *vide supra*. According to W. Biltz, when 1 c.c. of a colloidal soln. of cadmium sulphide is treated with two or three drops of a colloidal soln. of **ferric hydroxide**, yellowish-brown floccules are formed; colloidal **aluminium hydroxide**, **chromic hydroxide**, or **zirconium hydroxide** gives a precipitate; and colloidal **cerium hydroxide** gelatinizes the soln. Plant and animal fibres are coloured yellow by a colloidal soln. of cadmium sulphide. L. Vanino and F. Hartl found that when 100 c.c. of a colloidal soln. of cadmium sulphide with 0.02 grm. of cadmium sulphate are treated with 3 grms. of barium sulphate, a colourless filtrate is obtained.

There are doubts about the individuality of **zinc hydrosulphide**, $\text{Zn}(\text{SH})_2$, or **cadmium hydrosulphide**, $\text{Cd}(\text{SH})_2$. J. Thomsen added 2 eq. of sodium hydrosulphide to one of zinc sulphate in aq. soln., and obtained an opalescent liquid which when treated with acids or sodium hydroxide gave a precipitate which he regarded as *wahrscheinlicher* zinc hydrosulphide. When the soln. is allowed to stand some hours, a precipitate is formed which redissolves when heated; he said it is probable that sodium sulphide and hydrosulphide behave similarly towards a soln. of zinc sulphate, and that zinc hydrosulphide dissolves in a soln. of sodium hydrosulphide like zinc hydroxide does in a soln. of sodium hydroxide. V. von Zotta stated that J. Thomsen's hydrosulphide has the formula $\text{Zn}(\text{SH})_2 \cdot 2\text{ZnS}$, or $\text{Zn}_3\text{H}_2\text{S}_4$. The production of this substance explains the evolution of hydrogen sulphide when an alkali hydrosulphide is added to zinc sulphate. H. Baubigny prepared the hydrosulphide from soln. of the acetate either by the action of hydrogen sulphide or ammonium sulphide. According to M. Berthelot, the precipitation is incomplete with the chloride or sulphate. The supposed zinc and cadmium hydrosulphides have been studied by S. E. Linder and H. Picton. J. M. van Bemmelen said that the supposed zinc or cadmium hydrosulphide is not a true chemical compound. According to L. W. McCay, zinc sulphide or zinc hydrosulphide precipitated from alkaline soln. of zinc salts by alkali hydrosulphide is soluble in an excess of the reagent much as zinc oxide or hydroxide dissolves in alkali hydroxide. The analogy leads to the assumption that an alkali sulphozincate, R_2ZnS_2 , is formed: $\text{Zn}(\text{SH})_2 + 2\text{RSH} = \text{R}_2\text{ZnS}_2 + 2\text{H}_2\text{S}$. The **alkali sulphozincate**, however, must be very unstable, for when conc. mineral salts are added, zinc sulphide or hydrosulphide gradually separates out in a slimy form. Zinc hydrosulphide precipitated from alkaline soln. by hydrogen sulphide, dissolves when the current of gas is continued for some time.

H. Schiff²⁶ treated a neutral soln. of a zinc salt with potassium pentasulphide and obtained a white mass, which, when washed, pressed, and dried over sulphuric acid, furnished a straw-yellow anhydrous mass. The analyses agreed with **zinc pentasulphide**, ZnS_5 . When heated in the absence of air, it decomposes into the monosulphide and sulphur; it also dissolves in acids with the evolution of hydrogen sulphide and the separation of sulphur. He also prepared orange-yellow **cadmium**

pentasulphide, CdS_5 , in a similar manner. O. Follenius believes that these products are mixtures of the monosulphides and free sulphur.

§ 16. Zinc and Cadmium Sulphates

G. W. Schwartz¹ has stated that zinc sulphate, or artificial white vitriol was known near the end of the thirteenth or the beginning of the fourteenth century,

but, according to J. Beckmann, it was not known before the middle of the sixteenth century, and it was first made at Rammelsberg or at Goslar. He said that the white vitriol which is produced in the mines at Rammelsberg in the form of icicles gave rise to the discovery and manufacture of the salt. The native white vitriol was packed in casks and called *Gogkelgut*. The salt was known as *Gallitzenstein*, *Golitzstein*, and *Calitzenstein*. These terms were also applied to green vitriol—possibly derived from galls, because vitriol and galls were used in making inks and in dyeing. The colour of the early preparations mentioned by H. Boerhaave were green, owing to the presence of impurities. G. Agricola called it *charcanthum candidum* or *atramentum sutorium*; C. Gesner called it *atramentum album*, and it was later called *Erzalum*, *vitriolum album*, *white vitriol*, *white copperas*, *zinc vitriol*, etc. N. Lemery (1735), L. Lemery (1707), and E. F. Geoffroy knew that sulphuric acid is one of its constituents, but they were not clear about the basic component. J. F. Henckel found that white vitriol contains zinc, and G. Brandt showed that it consists of sulphuric acid and zinc oxide. J. Hellot confirmed this conclusion.

According to A. Breithaupt,² microscopic crystals of zinc sulphate occur as the mineral *zincosite* in Sierra Almagrera (Spain); it was said to be isomorphous with lead and barium sulphates. H. Brandhorst found crystals of zinc sulphate in the flue dust of furnaces roasting zinc sulphide ores. There are doubts about A. Breithaupt's mineral, but heptahydrated zinc sulphate, $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$, occurs as the mineral *goslarite*, in the passages of mines—Goslar (Harz), Schemnitz (Hungary), Fahlun (Sweden), Holywell (Wales), etc.—and is formed by the decomposition of zinc blende. It was described by J. G. Wallerius; and analyzed by F. S. Beudant, and M. H. Klaproth. F. S. Beudant called the mineral *gallitzenite*, but W. Haidinger's term *goslarite* is generally employed. A form of *goslarite* in which zinc is partially replaced by ferrous iron is called *ferrogoslarite*. It is found in the drainage of some mines. L. Palmeri found crystals of the heptahydrated zinc sulphate among the sublimation products from Vesuvius.

In addition to anhydrous zinc sulphate, ZnSO_4 , hydrates have been reported containing 1, 2, $3\frac{1}{2}$, 5, 6, and 7 mols of water per mol of sulphate; and besides anhydrous **cadmium sulphate**, CdSO_4 , hydrates with $\frac{1}{2}$, 1, $1\frac{1}{2}$, $2\frac{1}{2}$, $2\frac{3}{4}$, 3, 4, 7, and 9 mols of water per mol of sulphate have been reported. Not all these hydrates can be regarded as chemical individuals. H. G. Denham circulated a soln. of cadmium sulphate over granulated cadmium for several days, and, after 40 hrs., fern-like crystals of cadmium were observed to separate at the bottom of the column of cadmium. It was therefore inferred that the bivalent cadmium is reduced to univalent cadmium: $\text{Cd} + \text{CdSO}_4 = \text{Cd}_2\text{SO}_4$, and that the **cadmium subsulphate**, Cd_2SO_4 , in soln. immediately decomposes into ordinary cadmium sulphate and the metal.

Anhydrous zinc sulphate is made by heating the hydrated salt; H. O. Hofman and co-workers³ said that 263° was the lowest temp. at which the salt can be dehydrated, and that after 2 grms. have been heated 30–40 hrs., 0.24 per cent. of water still remains. F. Krafft stated that the heptahydrate can be completely dehydrated in vacuo at 210° . A. de Schulten showed that crystals of anhydrous zinc or cadmium sulphate can be obtained by the slow evaporation of a soln. of the sulphates in conc. sulphuric acid; and anhydrous cadmium sulphate, by melting cadmium with ammonium or potassium persulphate. P. Klobb made anhydrous zinc sulphate by heating a mixture of ammonium sulphate and the heptahydrate, and A. J. Boulton by heating zinc earths, zinc oxide, etc., with ammonium sulphate in closed vessels at 300° – 500° ; and the International Chemical Co., by melting and roasting zinc sulphide with alkali hydrosulphate.

A soln. of zinc sulphate is obtained by dissolving the metal or the oxide⁴ in dil. sulphuric acid. Similar results are obtained with the carbonate and hydroxide. Zinc sulphate is made by roasting zinc blende and evaporating the soln. in dil. acid for crystallization. F. Ellershausen and R. W. Western recommended extracting the roasted ore with a soln. of ammonium sulphate in sulphuric acid. J. Knobloch

recommended purifying the boiling soln. of zinc sulphate by adding sufficient zinc fluoride to precipitate all the calcium and magnesium, but an excess should not be used, or if used should be removed by gypsum. Zinc oxide, mixed with water, is then added, the whole is left for a day, with occasional stirring, then filtered, acidified with a little sulphuric acid, and the filtrate evaporated till it begins to crystallize. If the crystals contain chlorine, it is necessary to recrystallize from water. E. van de Vyvere, F. Stolba, H. Prunier, and C. J. Bender have described methods for the purification of zinc sulphate—*vide* purification of zinc. C. R. Kuzell and J. R. Marston discussed the purification of zinc sulphate from arsenic. The crystallization of the aq. soln. of zinc sulphate at ordinary temp. furnishes the **heptahydrated zinc sulphate**, $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$; and soln. of cadmium sulphate, **octotrihydrated cadmium sulphate**, $\text{CdSO}_4 \cdot \frac{8}{3}\text{H}_2\text{O}$. E. A. Partridge prepared highly purified cadmium sulphate by adding a small excess of sulphuric acid to a soln. of purified cadmium nitrate, evaporating to dryness, and heating the mass until the fumes of sulphur dioxide ceased to be evolved. The residue is then extracted with water, the soln. crystallized, and the crystals dried for 6 hrs. at 200° .

According to C. von Hauer,⁵ 100 parts of a sat. soln. of zinc sulphate at 18° – 20° contain 35.36 parts of the anhydrous salt. Other observations on the solubility of zinc sulphate have been made by C. J. B. Karsten, E. Tobler, A. B. Poggiale, H. G. F. Schröder, H. Schiff, G. J. Mulder, etc. L. C. de Coppet, F. Rüdorff, F. Guthrie, and G. Bruni made observations at low temp. The best representative values for the percentage solubility in water, with the corresponding solid phases are,

Solid phase	-5°	0.1°	9.1°	15°	25°	35°	39°	
$\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$	28.21	28.54	32.01	33.81	36.67	39.98	41.21	per cent. ZnSO_4

H. L. Callendar and H. T. Barnes give 39.0° for the transition temp. of the hepta- and hexa-hydrates; and A. Étard gives 70.0° for the transition temp. of the hexa- and mono-hydrates.

Per cent. ZnSO_4	50°	70°	80°	90°	100°	120°	137°	169°	171°
	43.45	47.5	46.4	45.5	44.7	41.7	38.0	30.0	29.0
Solid phase	$\text{ZnSO}_4 \cdot 6\text{H}_2\text{O}$				$\text{ZnSO}_4 \cdot \text{H}_2\text{O}$				

L. C. de Coppet gives for the unstable system at -7.15° and -10.1° , respectively 38.10 and 30.70 per cent. ZnSO_4 with ice as the solid phase; and E. Cohen gives for the unstable hexahydrate at -5° , 0.1° , and 25° , respectively 32.01, 33.10, and 38.93 per cent. ZnSO_4 . The data are plotted in Fig. 48, to show the ranges of stability of the different hydrates.

FIG. 48.—Solubility Curve of Zinc Sulphate.

H. L. Callendar and H. T. Barnes represent the percentage solubility, S , between 0° and 39° , by $S = 29.5 + 0.270\theta + 0.00068\theta^2$. E. Cohen also calculated formulæ for the solubility over definite ranges of temp. C. R. Schulze noted a maximum in the solubility curve between 10° and 60° , and A. Étard followed the curve for the decreasing solubility of zinc sulphate up to 171° . E. Cohen and L. R. Sinnige give 57.95 per cent. for the solubility of heptahydrated zinc sulphate at 25° to 26° under one atm. press.; 58.38 per cent. under 500 atm. press.; and 57.55 at 1000 atm. press.

According to R. Schindler,⁶ and J. B. Hannay, and T. Graham, **monohydrated zinc sulphate**, $\text{ZnSO}_4 \cdot \text{H}_2\text{O}$, is formed when the heptahydrated salt is dried in air at 100° , or in vacuo over sulphuric acid at 20° . F. Kraft also made the monohydrate by 15 hrs.' drying in a vacuum desiccator at a summer's temp. Crystals of the monohydrate also separate when the sulphate is deposited from a boiling sat.

phate, $\text{ZnSO}_4 \cdot \text{H}_2\text{O}$, is formed when the heptahydrated salt is dried in air at 100° , or in vacuo over sulphuric acid at 20° . F. Kraft also made the monohydrate by 15 hrs.' drying in a vacuum desiccator at a summer's temp. Crystals of the monohydrate also separate when the sulphate is deposited from a boiling sat.

soln.—*vide* Fig. 48—the composition of the crystals, said E. Cohen, remains constant when allowed to stand on the water-bath for a long time. A. Étard made the monohydrate by heating to 200° an excess of conc. sulphuric acid with a sat. soln. of zinc sulphate, and cooling. R. Schindler found that crystals of the heptahydrate at 50° crumble to a white powder, which he regarded as **dihydrated zinc sulphate**, $\text{ZnSO}_4 \cdot 2\text{H}_2\text{O}$; he also obtained a crystalline crust of crystals with the same composition by evaporating at 100°, a soln. of zinc sulphate with an excess of sulphuric acid. A. Étard also obtained crystals of the dihydrate from a soln. of zinc sulphate at a temp. over 81°. J. B. Hannay, and O. B. Kühn obtained a similar product as a crystalline powder by adding sulphuric acid to a boiling conc. soln. of zinc sulphate. E. F. Anthon, and R. J. Kane obtained rhombohedral crystals of **hemiheptahydrated zinc sulphate**, $\text{ZnSO}_4 \cdot 3\frac{1}{2}\text{H}_2\text{O}$, mixed with crystals of the heptahydrate, by allowing a conc. aq. soln. of zinc sulphate containing a little free acid, to stand for some time at 0°. J. B. Hannay's study of the heating curves led him to suppose that this salt is **trihydrated zinc sulphate**, $\text{ZnSO}_4 \cdot 3\text{H}_2\text{O}$. R. Schindler obtained a crust of crystals of what he regarded as **pentahydrated zinc sulphate**, $\text{ZnSO}_4 \cdot 5\text{H}_2\text{O}$, by evaporating the soln. of zinc sulphate between 40° and 50°. O. B. Kühn also prepared the same compound by boiling the finely powdered heptahydrate with alcohol of sp. gr. 0·856; the pasty mass solidifies to a hard crystalline substance with a waxy fracture. J. B. Hannay obtained the pentahydrate in a similar manner. E. Mitscherlich, and J. B. Hannay found that crystals of **hexahydrated zinc sulphate**, $\text{ZnSO}_4 \cdot 6\text{H}_2\text{O}$, separate from aq. soln. at a temp. over 30°—J. C. G. de Marignac said 50°–55°. According to E. Mitscherlich, also, a crystal of the heptahydrate when heated over 52° becomes opaque because it is thereby converted into an aggregate of small crystals of the hexahydrate; E. Wiedemann converted the crystals of the heptahydrate into those of the hexahydrate by heating at 69°. E. Cohen gave 38·75° for the transition temp. by vol. measurements, 38·50° by solubility measurements, and 39·0° by conductivity measurements. H. L. Callendar and H. T. Barnes gave 39·95° for the transition temp.; H. T. Barnes, and H. T. Barnes and H. L. Cooke gave 39·95° from solubility determinations, and 38·75° from measurements on the e.m.f. of a Clarke's cell. L. de Boisbaudran observed a change in the character of the crystals of the heptahydrate between 50° and 60°; and R. Hollmann, at about 40°.

The solubility of cadmium sulphate in water has been measured by P. Kohnstamm and E. Cohen,⁷ H. von Steinwehr, J. Koppel and A. Gumpertz, H. B. Holsboer, etc. R. Mylius and R. Funk's values for the percentage solubility for the heptahydrate as solid phase, are 44·5, 46·1, and 49·5 per cent. CdSO_4 respectively at –17°, –10°, and –6°. The best representative values for the $2\frac{2}{3}$ hydrate and the monohydrate are:

	–18°	0°	20°	40°	74°	77°	85°	100°	112°
CdSO_4 . . .	43·35	43·01	43·37	43·99	46·70	42·2	39·6	37·8	37·0
Solid phase . . .	$\text{CdSO}_4 \cdot 2\frac{2}{3}\text{H}_2\text{O}$					$\text{CdSO}_4 \cdot \text{H}_2\text{O}$			

The transition point for $\text{CdSO}_4 \cdot 2\frac{2}{3}\text{H}_2\text{O}$ by F. Mylius and R. Funk is 74°, and for $\text{CdSO}_4 \cdot \text{H}_2\text{O} \rightleftharpoons \text{CdSO}_4 + \text{H}_2\text{O}$ is 112°; for the latter, N. Worobieff gave 104°. A. Étard's values at 120°, 160°, and 200° are respectively 31·50, 16·70, and 2·25 per cent. ZnCO_3 , and the solid phase was not determined. The observed results are shown in Fig. 49, which shows the ranges of stability of the different hydrates. E. Cohen and L. R. Sinnige found for the solubility at 1, 500, and 1000 atm. press. respectively 76·80 (25°), 77·85 (25°), and 78·79 (25·6°) per cent. CdSO_4 . P. Kohnstamm and E. Cohen reported a change in the solubility curve of cadmium sulphate in water at 15°, but H. von Steinwehr found the curve to be continuous between 13·7° and 25°. E. Cohen and J. J. Wolters found a minimum in the solubility curve of $\text{CdSO}_4 \cdot 2\frac{2}{3}\text{H}_2\text{O}$ at about –9°. The number of grams of CdSO_4 per 100 grms. of sat. soln. in the neighbourhood of this temp. was found to be 43·047 at –3·00°; 43·020 at –6·00°; 43·008 at –9·00°; and 43·029 at –12·00°.

O. B. Kühn⁸ prepared crystals of what have been regarded as **hemihydrated cadmium sulphate**, $\text{CdSO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$, by decomposing a third part of a soln. of cadmium sulphate with potassium hydroxide, and boiling the product with the remaining two-thirds of the soln.

FIG. 49.—Solubility Curve of Cadmium Sulphate.

According to the same authority, crusts of ill-defined crystals of **monohydrated cadmium sulphate**, $\text{CdSO}_4 \cdot \text{H}_2\text{O}$, are obtained by evaporating a soln. of cadmium sulphate containing an excess of sulphuric acid; and C. von Hauer obtained the same hydrate by adding conc. sulphuric acid to a boiling soln. of cadmium sulphate. H. Lescœur added an equal vol. of sulphuric acid to a sat. aq. soln. of the sulphate. F. Mylius and R. Funk obtained crystals by evaporating the neutral aq. soln. between 80° and 100°. H. C. Jones and H. P. Bassett, and N. Worobieff crystallized the soln. at 103° to 104°—*vide* Fig. 49. G. Wyruboff prepared the monohydrate by heating the ordinary sulphate with twice the amount of sulphuric acid at 30°–40°, if more sulphuric acid be used, the crystallization is conducted at a lower temp. N. Worobieff claimed to have made monoclinic crystals of **hemitrihydrated cadmium sulphate**, $\text{CdSO}_4 \cdot 1\frac{1}{2}\text{H}_2\text{O}$, by crystallization from a soln. of zinc-free cadmium oxide in dil. sulphuric acid. **Octotrihydrated cadmium sulphate**, $\text{CdSO}_4 \cdot 2\frac{2}{3}\text{H}_2\text{O}$, crystallizes from sat. soln. at ordinary temp. J. W. Retgers suggests that the octotrihydrate is really trihydrated cadmium sulphate, $\text{CdSO}_4 \cdot 3\text{H}_2\text{O}$, and this is not outside the limits of the experimental errors in the various analyses which have been reported. F. Stromeyer's observations agree with the formula $\text{CdSO}_4 \cdot 4\text{H}_2\text{O}$; C. F. Rammelsberg's, N. Worobieff's, and H. Kopp's with $\text{CdSO}_4 \cdot 3\text{H}_2\text{O}$; C. von Hauer's with $\text{CdSO}_4 \cdot 2\frac{2}{3}\text{H}_2\text{O}$. F. Mylius and R. Funk consider that **tetrahydrated cadmium sulphate**, $\text{CdSO}_4 \cdot 4\text{H}_2\text{O}$, may possibly exist since cadmium sulphate forms mixed crystals with tetrahydrated manganese sulphate. H. Lescœur also reported the formation of the tetrahydrate. H. Rose obtained crystals of what he regarded as **hemipentahydrated cadmium sulphate**, $\text{CdSO}_4 \cdot 2\frac{1}{2}\text{H}_2\text{O}$, by crystallization from a hot soln. of the sulphate—F. Mylius and R. Funk doubt the existence of this hydrate. According to F. Mylius and R. Funk, a crystalline powder of **heptahydrated cadmium sulphate**, $\text{CdSO}_4 \cdot 7\text{H}_2\text{O}$, is obtained by rapidly cooling to 0° a soln. of cadmium sulphate, sat. at 70°, and then lowering the temp. to –20°, and rubbing the sides of the vessel with a glass rod. H. C. Jones and H. P. Bassett claimed to have made **enneahydrated cadmium sulphate**, $\text{CdSO}_4 \cdot 9\text{H}_2\text{O}$, by crystallization at a very low temp. The product is possibly a mixture of the cryohydrate and ice. *The mono-, hexa-, and hepta-hydrates of zinc and cadmium sulphates, and the octotrihydrate of cadmium sulphate are the only ones whose individuality can be regarded as definitely established.*

A. de Schulten⁹ prepared **crystals** of anhydrous zinc and cadmium sulphates in rectangular plates; the crystals of the two salts are isomorphous, and belong to the rhombic system. P. Klobb obtained colourless octahedral crystals of zinc sulphate. According to G. Wyruboff, the crystals of monohydrated cadmium sulphate belong to the monoclinic system, and have axial ratios $a : b : c = 1.0976 : 1 : 1.7180$, and $\beta = 90^\circ 13'$. C. F. Rammelsberg also found the crystals of octotrihydrated cadmium sulphate to belong to the monoclinic system, and have axial ratios $a : b : c = 0.7992 : 1 : 0.6900$, and $\beta = 117^\circ 58'$; C. F. Rammelsberg said the crystals are isomorphous with didymium and yttrium sulphates; H. Kopp, and H. de Sénarmont also have made observations on these crystals. G. Wyruboff found that the prismatic crystals of hexahydrated zinc sulphate belong to the monoclinic system and have axial ratios $a : b : c = 1.3847 : 1 : 1.6758$, and $\beta = 98^\circ 12'$; J. C. G. de Marignac showed that the crystals are isomorphous with those of the analogous salts of magnesium, nickel, and cobalt. E. Mitscherlich supposed the hexahydrate to be a dimorphous

form of the heptahydrate. L. de Boisbaudran found that when a soln. of zinc sulphate is seeded with the tetragonal form of hexahydrated nickel sulphate, a tetragonal zinc salt is produced. The crystals of goslarite, or heptahydrated zinc sulphate, are bisphenoidal, belong to the rhombic system, and, according to H. J. Brooke, have axial ratios $a : b : c = 0.9804 : 1 : 0.5631$. C. F. Rammelsberg studied mixed crystals of heptahydrated zinc sulphate with the isomorphous salts of magnesium, manganese, copper, and iron. This subject has also been studied by K. van Hauer, H. Schiff, L. de Boisbaudran, J. Lefort and J. Nicklès, M. Schäuuffele, H. Vohl, C. Weltzien, J. Grailich, J. M. Thomson, C. Frenzel, etc. According to J. W. Retgers, the crystals of heptahydrated cadmium sulphate are isomorphous with the corresponding heptahydrated ferrous sulphate. W. Haidinger, and H. Reinsch have reported modifications in the form of heptahydrated zinc sulphate, and E. von Fedoroff obtained an unstable easily soluble monoclinic variety from undercooled soln. According to H. G. F. Schröder, an easily soluble form separates from undercooled soln. protected from air by cotton wool, while if the soln. be crystallized while exposed to the air, or if the crystals be kept in contact with air, a less soluble form is produced.

The **specific gravity** of anhydrous zinc sulphate was given by C. J. B. Karsten,¹⁰ and E. Filhol as 3.400; C. Pape gave 3.436 (16°); P. A. Favre and C. A. Valson, 3.40; H. G. F. Schröder gave 3.551; T. E. Thorpe and J. I. Watts, 3.6235 (15°); and L. Playfair and J. P. Joule, 3.681 (3.9°). H. G. F. Schröder gave 4.447 for anhydrous cadmium sulphate. For monohydrated zinc sulphate, C. Pape gave 3.215 (16°); H. G. F. Schröder, 3.076; L. Playfair, 3.259; and T. E. Thorpe and J. I. Watts, 3.2845 (15°). H. J. Buignet gave 2.939 for monohydrated cadmium sulphate. T. E. Thorpe and J. I. Watts gave 2.958 (15°) for dihydrated zinc sulphate; 2.206 (15°) for the pentahydrate; and 2.072 (15°) for the hexahydrate. For the last-named salt, L. Playfair gave 2.056. For octotritahydrated cadmium sulphate, C. H. D. Bödeker gave 3.05 (12°). The number for heptahydrated zinc sulphate reported by J. H. Hassenfratz is 1.912; by L. Playfair and J. P. Joule, 1.931; by E. Filhol, 2.036; by H. Schiff, 1.953; by H. J. Buignet, 1.957; by P. A. Favre and C. A. Valson, 1.981; by F. Stolba, 1.9534; by S. Holker, 1.976 (15.5°); by C. Pape, 1.901 (16°); by H. G. F. Schröder, 1.984; by H. Töpsöe and C. Christiansen, 2.008; by W. C. Smith, 1.961; and by T. E. Thorpe and J. I. Watts, 1.974 (15°).

The sp. gr. of soln. of zinc sulphate measured at 15° by G. T. Gerlach,¹¹ when the conc. of the soln. is expressed by the percentage amount of $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$, are :

Conc. .	5	10	15	20	25	30	40	50	60
Sp. gr. .	1.0288	1.0593	1.0905	1.1236	1.1574	1.1933	1.2709	1.3532	1.4451

Other measurements have been made by H. Schiff, H. L. Callendar and H. T. Barnes, F. Kohlrausch and W. Hallwachs, J. Wagner, J. A. Ewing and J. G. McGregor, C. Charpy, H. C. Jones and F. H. Getman, P. A. Favre and C. A. Valson, W. W. J. Nicol, H. Schiff, C. R. A. Wright and C. Thompson, J. I. Watts, C. Bender, etc. The variation in the sp. gr. of soln. with temp. was measured by O. Grottrian, F. Fouqué, C. Forch, and J. de Lannoy, and their data show the coeff. of thermal expansion of soln. of zinc sulphate — *vide infra*. I. Traube gave for the mol. vol.

Per cent. ZnSO_4 .	2.80	5.61	11.22	16.83	28.08	33.66	100
Mol. vol. .	0.5	0.5	3.4	5.3	11.4	13.9	46.3
Per cent. $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$.	5	10	20	30	40	60	100
Mol. vol. .	126.6	126.7	129.5	132.4	134.3	140.0	142.8

W. Hallwachs, and W. W. J. Nicol also made observations on the mol. vol. of soln. of zinc sulphate. According to R. Broom, when a soln. of 48.36 parts of zinc sulphate in 100 of water is mixed with an equal vol. of water, a contraction of 0.835 per cent. occurs. F. Kohlrausch and W. Hallwachs reported a marked condensation in crystallizing from water. O. Grottrian found for the sp. gr. of soln. of cadmium sulphate at 18°, when the conc. is expressed in per cent. of CdSO_4 :

Conc.	0.282	1.011	5.08	10.11	25.03	36.07
Sp. gr.	1.0085	1.0085	1.0495	1.1039	1.2935	1.4756

Other determinations have been made by C. A. Valson, J. Kanonnikoff, I. Traube, H. Jahn, O. Schönrock, M. le Blanc and P. Rohland, E. Cohen and L. R. Sinnige, F. Fouqué, F. J. Wershoven, J. Wagner, J. G. McGregor, H. C. Jones and F. H. Getman, R. de Muynck, C. M. Pasea, C. R. A. Wright and C. Thompson, etc. According to E. Irueste, for a soln. of cadmium sulphate of sp. gr. D , at 15° , when that of water at 15° is D_0 , the soln. will contain $0.91660(D-D_0)-0.22101(D-D_0)^2$ grms. of salt per gram of soln. O. Grotrian measured the **fluidity** of soln. of zinc sulphate; G. Quincke,¹² the **specific cohesion**; and C. A. Valson, W. Grabowsky, E. Klupathy, P. Volkmann, and I. Traube the **rise in capillary tubes** of different diameter. The viscosities of equimol. soln. of magnesium and zinc sulphates were found by J. Wagner to be nearly the same, and he gave, at 25° , for the **viscosity** of zinc and cadmium sulphates, water unity,

Viscosity ZnSO_4	$\frac{1}{2}N$ - 1.3671	$\frac{1}{2}N$ - 1.1726	$\frac{1}{2}N$ - 1.0824	$\frac{1}{2}N$ - 1.0358
Viscosity CdSO_4	1.3476	1.1574	1.0780	1.0335

Other measurements were made by S. Arrhenius, L. Grossmann and A. A. Blanchard. The **capillary constant**, of zinc sulphate soln., sp. gr. 1.153, at 20° , was found by E. Klupathy to be 11.9; and G. Quincke, I. Traube, and P. Volkmann made similar observations. C. Forsch, A. Brümmer, H. Sentis, P. Volkmann, and I. Traube made observations on the **surface tension** of soln. of zinc sulphate; and N. E. Dorsey found for soln. of normality N , in dynes per cm.:

N	0	0.066	0.108	0.286	0.372	0.414
σ	73.39	73.30	73.44	73.90	73.79	73.91

I. Traube measured the surface tension of soln. of zinc sulphate in ethyl alcohol. The coeff. of **diffusion** was found by J. J. Coleman to be smaller with soln. of zinc sulphate than with soln. of magnesium sulphate. J. C. Graham, J. H. Long, N. van de Wall, J. Schuhmeister, H. F. Weber, B. von Tietzen-Hennig, and C. Lüdeking have measured the velocity of diffusion of soln. of zinc sulphate. W. Seitz found $k=0.2355$ for soln. with 1.0 mol of ZnSO_4 per litre at 14.77° ; and G. Thovet found $k=0.50, 0.47, 0.36$, and 0.33 respectively at 19.5° for soln. with 0.025, 0.050, 0.55, and 2.95 mol per litre. W. Seitz and J. J. Coleman of soln. of cadmium sulphate; the former found $k=0.246$ at 19° for soln. with two mols of CdSO_4 per litre. O. Schmidt found for the **compressibility**, β , of aq. soln. of zinc sulphate between 16° and 17.5° :

Per cent. ZnSO_4	7.5	13.5	17.5	32.5	41.0
$\beta \times 10^6$	45.1	41.0	41.6	32.3	26.4

W. Watson also measured this constant. When crystals of zinc heptahydrate were warmed from 18° to 40° , G. Wiedemann found a regular increase in vol., at 40° there is a marked change attended by the loss of a mol of water; between 40° and 69° , there is again a regular expansion; and at 69° there is an abrupt contraction. There is a marked expansion between 69° and 100° , and a white powder is formed. The relative vol. of aq. soln. of zinc sulphate at different temp. $\delta v=(v-1)10^5$; or $v=(v_0+\delta v)10^{-5}$ when $v_0=100,000$, as measured by C. Forch, is:

	5°	10°	15°	20°	30°	40°
0.500N-	27	84	168	278	564	930
1.000N-	55	135	239	364	672	1050
1.999N-	99	213	344	491	830	1227

and his values for the **coefficient of thermal expansion** between 0° and 15° for $\frac{1}{2}N$ -, N -, and $2N$ -soln. of zinc sulphate, are 0.000054, 0.000110, and 0.000195 respectively. R. Meyer measured the thermal expansion of conc. soln. of zinc sulphate. J. de Lannoy¹³ obtained for $v \times 10^{-5}$:

Per cent. $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$	20°	40°	60°	80°
4	215	860	1800	3020
10	326	976	1902	3103
20	438	1148	2100	3290
30	550	1291	2251	3390

W. W. J. Nicol found the apparent vol. of supersaturated soln. of zinc sulphate to change quite regularly between 20° and 30°. G. Jäger¹⁴ represented the **thermal conductivity** of 16 and 32 per cent. soln. of zinc sulphate by 95.3 and 91.5 respectively when that of water is 100. H. F. Weber gave for the absolute conductivity, k , at 4.5°:

Sp. gr.	1.134	1.272	1.362	1.362	1.362
k	0.00118	0.00116	0.00115	0.00129 (23.4°)	0.00144 (45.2°)

C. G. Lundquist, and L. Grätz, also made measurements of this constant.

C. Pape¹⁵ gave 0.328 for the **specific heat** of heptahydrated zinc sulphate between 17° and 23°; H. Kopp gave 0.347 between 15° and 30°; H. Schottky, 0.3485 between 1° and 34°; E. Cohen and co-workers, 0.3184 between 18.5° and 22.5°; and F. Pollitzer gave for the mol. ht. of $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$.

Mol. ht.	-191°	-190°	-187°	-185°	-72°	-69°	-65°
	30.34	31.65	31.76	31.26	67.0	66.9	67.9

J. C. G. de Marignac found the sp. ht. of a soln. of a mol of zinc sulphate with 50, 100, and 200 mols H_2O to be respectively 0.8420, 0.9106, and 0.9523 between 20° and 52°. E. Cohen and co-workers found the sp. ht. of octotritahydrated cadmium sulphate to be 0.2008 at 20°, and the mol. ht. 5.50. Measurements were made by H. Teudt, E. Cohen and A. L. T. Mösveld, J. Thomsen, S. Pagliani, H. Suominen, and H. F. Weber. The sp. ht. of soln. of one mol of cadmium sulphate with n mols of water was found to be

n	500	200	100	50	25	17	14.9	14.4
Sp. ht.	0.972	0.940	0.893	0.813	0.696	0.638	0.615	0.610

According to H. St. C. Deville and H. Debray,¹⁶ the **action of heat** on anhydrous zinc sulphate results in the formation of a basic sulphate, and at an incipient white heat, zinc oxide is formed. J. L. Gay Lussac made some observations on this subject. G. H. Bailey said that zinc sulphate begins to decompose at 427°. H. O. Hofman and co-workers said that the temp. of incomplete decomposition is 528°, and of complete decomposition 739°, and there is no sign of a break in the decomposition curve such as might occur if a true basic salt were formed, and F. O. Doeltz and C. A. Graumann believe the alleged basic sulphate is a mixture of zinc oxide and sulphate; they add that the reaction $\text{ZnSO}_4 = \text{ZnO} + \text{SO}_3$ is reversible. L. and P. Wöhler and W. Plüddemann measured the decomposition press. of anhydrous zinc sulphate—*vide* the action of oxygen on zinc sulphide. H. Pommerenke found the decomposition of zinc sulphate occurs at a lower temp. if it be mixed with zinc oxide. W. A. Tilden gave 50° for the **melting point** of heptahydrated zinc sulphate; G. Wiedemann, 70.5°; G. Calcagni and D. Marotta, and O. Ruff and W. Plato gave 1000° for the m.p. of anhydrous cadmium sulphate, and the latter say that there is a marked thermal effect at 820°, indicating that some transformation is taking place; mixtures of cadmium sulphate and chloride gave a V-eutectic at about 569° and 85 molar per cent. of the chloride. E. Cohen found -3752 cal. for the **heat of fusion** of heptahydrated zinc sulphate; and he calculated -3609 cal. from J. Thomsen's data.

T. Graham, O. B. Kühn, and A. van der Toorn found that crystals of heptahydrated zinc sulphate effloresce in air, and at 100°, they lose $6\text{H}_2\text{O}$, and the remaining water is expelled at a red heat; T. Graham applied the term *saline water* to this portion of the water of crystallization which is not expelled except at a relatively high temp., and J. I. Pierre stated that all the water can be slowly expelled from the heptahydrate in a current of dry air at 110°. A. Frenzel drove off 39.75 of the

contained 43.90 per cent. of water by heating goslarite to 100°. H. Baubigny showed that the speed of efflorescence in air is directly proportional to the vap. press. The neutral salt effloresces until one of the lower hydrates is formed; but if acid, all the water can be removed in dry air. F. Krafft removed six mols of water in 15 hrs. at a summer's heat in vacuo, and all was expelled in vacuo at 210°. J. B. Hannay measured the speed of dehydration at 100°, and inferred that at lower temp. heptahydrated zinc sulphate is less stable than the corresponding magnesium sulphate. C. R. Schulze, W. Müller-Erbach, P. C. F. Frowein, and C. E. Linebarger have measured the **vapour pressure**, p , of hydrated zinc sulphate, and G. Wiedemann found in mm. of mercury:

	16.5°	30°	40°	50°	60°	70°	78.8°	88°
p	7.3	20.2	44.2	73.1	113.9	170.8	258.5	116.6

and P. C. F. Frowein gave for the maximum press. in mm. of mercury:

	$\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$				$\text{ZnSO}_4 \cdot 6\text{H}_2\text{O}$			
	18.00°	20.45°	25.15°	29.95°	17.85°	25.15°	29.95°	31.70°
p	8.046	10.075	14.697	2.389	7.633	13.286	18.826	21.075

H. Lescœur found the vap. press. curves furnished evidence of the existence of mono- and hepta-hydrated zinc sulphates.

A. van der Toorn showed that monohydrated zinc sulphate does not lose its water until the temp. exceeds 100°; T. Graham said the water is not lost even at 205°, but is given off near 238°; and T. Thomson, R. Schindler, and H. G. F. Schröder, found a little sulphuric acid is also lost at this temp. For the transformation of the hepta- into the hexa-hydrate see the preparation of the latter. According to F. Mylius and R. Funk, when the temp. of heptahydrated cadmium sulphate rises to 4°, it slowly decomposes, forming a mush which contains the octotritahydrate. The vap. press. of the last-named salt was measured by A. H. Pareau, by H. Precht and K. Kraut, and H. Lescœur. C. D. Carpenter and E. R. Jette found the transition temp. between the octo- and tri-hydrates to be 41.5°, and they also measured the vap. press. of the solid and sat. soln. Unlike C. von Hauer, F. Mylius and R. Funk found that crystals of monohydrated cadmium sulphate can be heated to 100° without change, but at 160°, the greater part of the combined water is expelled; they also obtained no signs of the intermediate formation of the hemihydrate of O. B. Kühn during the dihydration of the monohydrate. According to H. Lescœur, the dissociation press. of the monohydrate is 162 mm. at 174.5°, and immeasurably small at 0°. To summarize for the 6-7 hydrates at 25°, H. W. Foote and S. R. Scholes gave 13.6 mm.; P. C. F. Frowein, 14.6 mm.; W. C. Schumb, 15.34 mm.; H. Lescœur, 14.0; W. Müller-Erbach, 12.9 mm.; and G. Wiedemann, 14.5 mm. For the 1-6 hydrates, H. W. Foote and S. R. Scholes gave 12.8 mm.; P. C. F. Frowein, 13.2 mm.; W. Müller-Erbach, 11.7 mm.; and A. A. Noyes and L. R. Westbrook, 13.0 mm. For the 0-1 hydrates, H. W. Foote and S. R. Scholes gave 1.0 mm., and W. Müller-Erbach, 0.5 mm. E. Cohen and co-workers measured the effect of press. on the transition temp. of heptahydrated zinc sulphate.

G. Tammann¹⁷ measured the vap. press. of aq. soln. of zinc sulphate at 100°, and found that with soln. containing 15.59, 35.76, and 77.72 grms. of ZnSO_4 per 100 grms. of water, the vap. press. of water was lowered 10.0, 25.4, and 87.0 mm.; similarly with aq. soln. containing 16.46, 31.21, and 49.92 grms. of CdSO_4 per 100 grms. of water, the vap. press. of water was lowered 7.1, 12.9, and 23.3 mm. respectively. G. Tammann also measured the vap. press. of soln. of zinc sulphate in water at different temp. The lowering of the vap. press. has been measured by R. Emden, and J. Moser. J. Walker found the percentage mol. lowering of soln. with a mol of ZnSO_4 in 100 mols of water to be 1.26. For soln. of zinc sulphate containing n mol of ZnSO_4 in 1000 mols of water, H. Hausrath found for soln. with up to $n=0.03191$, and H. C. Jones and F. H. Getman for soln. with up to $n=2.032$ for the **lowering of the freezing point**, δf :

n	0.0002363	0.006259	0.01391	0.051	0.102	1.015	0.032
δf	0.000808°	0.01786°	0.03701°	0.094°	0.194°	1.753°	4.990°
$\delta f/n$	3.467	2.886	2.661	1.84	1.90	1.72	2.46

Values for aq. soln. of zinc sulphate have also been obtained by F. Rüdorff, N. Tarugi and G. Bombardini, F. M. Raoult, L. Kahlenberg, S. Arrhenius, L. C. de Coppet, G. Tammann, etc. For cadmium sulphate soln. with n mol of CdSO_4 per 1000 grms. of water, H. Hausrath found for soln. with up to $n=0.03120$, and H. C. Jones and F. H. Getman for soln. with up to $n=1.250$:

n	0.0002388	0.002685	0.03120	0.063	0.500	1.000	1.250
δf	0.0008417°	0.008189°	0.07556°	0.201°	1.259°	2.870°	4.160°
$\delta f/n$	3.526	3.055	2.421	3.19	2.52	2.87	3.23

Data were also obtained by F. M. Raoult, N. Tarugi and G. Bombardini, H. C. Jones and B. P. Caldwell, L. Kahlenberg, S. Arrhenius, D. J. Davis and R. E. Fowler, etc. F. Guthrie found the **cryohydric or eutectic temperature** of zinc sulphate to be -5° ; L. C. de Coppet gave -6.55° for soln. with 37.3 parts of ZnSO_4 in 100 parts of water; J. Koppel and A. Gumpertz found -6.5° ; G. Bruni, -6.4° ; for cadmium sulphate, J. Koppel and A. Gumpertz gave -16.8° ; and F. Mylius and R. Funk, -17° .

According to T. Griffiths, the **boiling point** of a sat. soln. of zinc sulphate—85 grms. of salt in 100 grms. of water—is 104.4° ; and G. T. Gerlach gave for soln. with w grms. of ZnSO_4 in 100 grms. of water:

w	13.1	25.0	37.7	45.4	53.9	61.0	74.9	85.7
B.p.	100.5°	101°	101.5°	102°	102.5°	103°	104°	105°

L. Kahlenberg found for the raising of the b.p. of water at 742–3 mm. press.:

$w \text{ ZnSO}_4$	2.886	10.139	22.202	30.47	35.18	39.83	41.30	44.56
Rise of b.p.	0.080°	0.266°	0.591°	0.899°	1.122°	1.381°	1.459°	1.671°
$w \text{ CdSO}_4$	4.563	10.972	20.662	27.777	36.76	41.28	47.38	53.47
Rise of b.p.	0.105°	0.215°	0.356°	0.494°	0.699°	0.820°	0.988°	1.164°

Other measurements with cadmium and zinc sulphates were made by N. Tarugi and G. Bombardini.

According to M. Berthelot,¹⁸ the **heat of formation** of anhydrous zinc sulphate is (Zn , S, 40), 229.6 to 233.4 Cals.; R. de Forcrand gave 230.91 Cals. and J. Thomsen gave for (Zn , O_2 , SO_2), 158.99 Cals. J. Thomsen also gave for (Cd , S, 40), 222.55 Cals., and M. Berthelot, 219.9 Cals. W. Nernst calculated the free energy of formation of hexa- and mono-hydrated zinc sulphates. L. and P. Wöhler and W. Plüddemann give 36 Cals. for the heat of decomposition $\text{ZnSO}_4 = \text{ZnO} + \text{SO}_3$. From his observations on the **heat of hydration** of zinc sulphate, J. Thomsen inferred that zinc sulphate forms hydrates with 1, 3, 4, 6, and 7 mols of water; and he gave 8.08 Cals. for the heat of hydration of $\text{CdSO}_4 \cdot 2\frac{2}{3}\text{H}_2\text{O}$. E. Cohen and co-workers gave 7.890 Cals. for the heat of hydration of CdSO_4 to form $\text{CdSO}_4 \cdot 2\frac{2}{3}\text{H}_2\text{O}$. For (Zn , O_2 , SO_2 , H_2O) J. Thomsen gave 167.47 Cals., and for the heat of soln., Q Cals. of $\text{ZnSO}_4 \cdot n\text{H}_2\text{O}$ in 400 mols of water at 18° ; and hence for the heat of hydration, Q_1 Cals., $\text{ZnSO}_4 + n\text{H}_2\text{O}$:

n	0	1	2	3	4	5	6	7
Q	10.434	9.950	7.604	5.258	3.513	1.335	-0.843	-4.260
Q_1	—	8.484	10.830	13.176	14.921	17.099	19.277	22.694

P. C. F. Frowein calculated 2.280 Cals. for the heat of soln. of the hexahydrate, and -3.44 Cals. for that of the heptahydrate. For the **heat of neutralization**, $\text{H}_2\text{SO}_{4\text{soln.}} + \text{ZnO} = \text{ZnSO}_{4\text{soln.}} + \text{H}_2\text{O} + 23.4$ Cals., J. C. G. de Marignac gave 22.3 Cals. J. Thomsen gave for the **heat of solution** of a mol of ZnSO_4 in 400 mols of water at 18° , 18.4 Cals.; and for $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$, -4.3 Cals.; P. A. Favre and C. A. Valson found for the heat of soln. of $\text{ZnSO}_4 \cdot n\text{H}_2\text{O}$:

n	0	1	3.75	4.46	4.55	6.17
Heat of soln.	9.289	4.812	2.205	1.354	1.198	-0.397 Cals.

and 5.455 Cals. for the heat of soln. of an eq. of cadmium sulphate in a litre of water. J. Thomsen gave 10.74 Cals. for the heat of soln. of a mol of cadmium sulphate in 400 mols of water, and 6.05 Cals. for the monohydrate. E. Cohen, W. D. Helder mann, and A. L. T. Mösveld, made observations on the heat of soln. of cadmium sulphate in soln. of the same salt. For the heat of soln. of $\text{CdSO}_4 \cdot \text{H}_2\text{O}$, P. A. Favre and C. A. Valson gave 6.2 Cals.; for $\text{CdSO}_4 \cdot 2\frac{3}{4}\text{H}_2\text{O}$, 2.7 Cals.; and for $\text{CdSO}_4 \cdot 3\text{H}_2\text{O}$, 3.062 Cals. J. Thomsen gave for the **heat of dilution** of a soln. of a mol of ZnSO_4 in 20 mols of water with 50, 100, and 200 mols of water respectively, 318, 369, and 385 Cals. Observations were also made by C. R. A. Wright and C. Thompson, J. H. Pollock, and L. C. de Coppet; for the heat of dilution of a soln. with $n\text{CdSO}_4 \cdot 100\text{H}_2\text{O}$ down to $0.25\text{CdSO}_4 \cdot 100\text{H}_2\text{O}$, C. R. A. Wright and C. Thompson gave:

n	1	2	3	4	5	6	7
Heat of dilution	75	275	450	635	825	1075	1450

According to A. des Cloizeaux,¹⁹ the crystals of hexa- and hepta-hydrated zinc sulphates and of octotrihydrated cadmium sulphate have a negative **double refraction**. H. Töpsøe and C. Christiansen found the **index of refraction** of hepta-hydrated zinc sulphate to be for the *C*-line, $\alpha=1.4544$, $\beta=1.4776$, and $\gamma=1.4812$; for the *F*-line, $\alpha=1.4568$, $\beta=1.4801$, and $\gamma=1.4836$; and for the *D*-line, $\alpha=1.45683$, $\beta=1.4801$, and $\gamma=1.48445$. H. C. Jones and F. H. Getman found the refractive index, μ , for soln. with *C* mols of zinc sulphate per litre:

<i>C</i>	0.051	0.102	0.203	0.406	0.609	1.015	1.624	2.032
μ	1.32711	1.32814	1.33110	1.33618	1.34149	1.35151	1.36543	1.37455

and for soln. with *C* mols of cadmium sulphate per litre:

<i>C</i>	0.063	0.125	0.250	0.500	0.625	0.875	1.000	1.250
	1.32790	1.33037	1.33535	1.34466	1.34912	1.35799	1.36101	1.37028

J. Kanonnikoff, C. Chéneveau, W. Hallwachs, H. Dijken, C. A. Valson, F. Fouqué, P. Barbier and L. Roux, M. le Blanc and P. Rohland, H. Jahn, R. de Muynck, etc., determined the optical constants for soln. of zinc and cadmium sulphates. O. Schönrock found the specific and **molecular rotation of the plane of polarization** for soln. of cadmium sulphate of sp. gr. 1.36289 ($16^\circ/4^\circ$) to be respectively 0.3423 and 3.955; and for soln. of sp. gr. 1.2421 ($16^\circ/4^\circ$), respectively 0.3597 and 4.156; H. Jahn gave for soln. of sp. gr. 1.1781 ($20^\circ/20^\circ$), the respective values 0.44748 and 5.17. J. R. Collins measured the **ultra-red absorption spectrum** of aq. soln. of the sulphate.

According to E. Wiedemann and G. C. Schmidt,²⁰ dried heptahydrated zinc sulphate gives a pale yellow **cathodo-luminescence**, with a prolonged after-glow which is white when the salt is heated; if one per cent. of manganese sulphate is present, the luminescence is an intense red, and the spectrum shows a red band. The property of showing **thermoluminescence** is lost in about a week. The photo-luminescence is red. J. A. Wilkinson found purified cadmium sulphate does not give cathodo-luminescence; the less pure salt has a yellow fluorescence, and H. Longchambon studied the spectrum of the **triboluminescence** of cadmium sulphate. E. Wiedemann and G. C. Schmidt found the spectrum of anhydrous cadmium sulphate shows intense lines in the yellowish-green, and feeble ones in the red and blue. A solid soln. of cadmium sulphate with one per cent. of zinc sulphate gives a blue thermoluminescence. G. C. Schmidt found the **canal rays** incite a yellow luminescence with calcined cadmium sulphate, but the property is lost with prolonged action. H. Greinacher found that **radioactive rays** raise the temp. of cadmium sulphate less than 0.01° . E. Goldstein studied the cathodo-luminescence of cadmium sulphate. Unlike the zinc halides, zinc sulphate when heated does not ionize the surrounding gas.

L. Kahlenberg's values²¹ for the eq. **electrical conductivity** of aq. soln. of zinc sulphate with one eq. of salt in *v* litres of water, are:

v	0.25	1	4	16	128	256	1024	2048	4096
λ_0°	7.1	16.3	24.7	32.2	47.5	52.9	61.0	64.4	65.4
λ_{95°	—	64.2	87.8	123.2	202.9	232.1	268.4	277.6	—

and for $v=8192$, $\lambda_0^\circ=65.9$. Other measurements have been made by F. Kohlrausch and co-workers, H. C. Jones and co-workers, C. Freund, C. Heim, H. V. Tartar and H. E. Keyes, A. Smits, J. Tollinger, N. Tarugi and G. Bombardini, G. Jäger, J. A. Ewing and J. G. MacGregor, E. Becker, E. N. Horsford, W. von Beetz, E. H. Marié-Davy, J. H. Long, S. Arrhenius, etc. L. Kahlenberg's values for the conductivity of soln. of cadmium sulphate are:

v	0.25	1	4	16	128	256	1024	2048	4096
λ_0°	6.7	15.0	21.3	29.5	45.6	50.5	59.4	62.4	63.4
λ_{95°	—	52.5	74.6	109.7	185.6	225.1	300.1	357.0	—

Other measurements have been made by O. Grottrian, C. J. J. Fox, F. J. Wershoven, N. Tarugi and G. Bombardini, H. C. Jones and co-workers; F. Kohlrausch and co-workers, G. Vicentini, etc. The effect of *temperature* on the conductivity of soln. of zinc sulphate has been studied by W. von Beetz, F. Kohlrausch, C. Heim, E. Cohen, J. Trötsch, and L. Grossmann. L. Kahlenberg's values for 0° and 95° are indicated above. H. C. Jones and A. P. West give for the temp. coeff. of the conductivity of soln. of zinc sulphate of dilution v :

v	2	8	16	32	128	512	1026	2048	8192
$0^\circ-15^\circ$	0.999	1.44	1.61	1.84	2.61	3.36	3.48	3.80	3.93
$15^\circ-25^\circ$	1.11	1.53	1.84	2.18	2.90	3.78	4.09	4.26	4.20

F. J. Wershoven, and O. Grottrian have studied the effect of temp. on the conductivity of soln. of cadmium sulphate. L. Kahlenberg's values at 0° and 95° are indicated above. The effect of *pressure* on the conductivity of soln. of zinc sulphate has been studied by J. Fink, B. Piesch, F. Körber, K. Rogoyski, O. Stern, and C. Freund. The electrical resistance of soln. decreases between 0° and 18° proportionally with the increase of press. up to 300 atm., but at higher press. the decrease is not so much. A. Hollard found that with less than 2 per cent. of dil. *sulphuric acid* in the soln. of zinc sulphate, the conductivity is increased; but with 3 per cent. of acid, the conductivity does not change. J. Kendall and co-workers measured the conductivity of zinc sulphate in anhydrous sulphuric acid. C. Lüdeking, and S. Arrhenius studied the effect of *gelatine*, and found no change; B. von Tietzen-Hennig studied the effect of *gelatine* and of *calcium sulphate*; H. Wolf, the effect of *acetic acid*, *alcohol*, and *tartaric acid*; S. Arrhenius, of methyl and ethyl alcohols, *ether*, and *acetone*; E. Wiedemann, of *glycerol*; E. Rimbach and O. Weber, of *lævulose*; and B. Sabat, of *radium*. A. A. Noyes studied the effect of *thallous chloride* on the conductivity of soln. of cadmium sulphate. R. Luther measured the conductivity of soln. of zinc and cadmium sulphates in methyl and ethyl alcohols. N. Isgarischey studied the polarization of soln. of zinc sulphate in the presence of *gelatine*, gum, and *sucrose*.

The **transport numbers** of zinc sulphate in aq. soln. have been investigated by J. F. Daniell and W. A. Miller, W. Hittorf, A. Chassy, J. Moser, S. Lussana, P. Straneo, G. Kümmell, and R. Gans; and of soln. of cadmium sulphate by C. L. Weber, A. Chassy, V. Gordon, G. Kümmell, B. D. Steele, H. Jahn, and S. Goldlust. A. Mutscheller measured the velocity of the ions in soln. of *gelatine* containing different conc. of zinc sulphate. G. N. Lewis and M. Randall calculated the activity coeff. of the ions of cadmium sulphate. The percentage **degree of ionization** α of soln. of zinc sulphate, was calculated from the electrical conductivity by H. C. Jones to be:

v	2	8	16	32	128	512	2048	4096
α at 0°	26.1	36.9	43.6	50.7	65.5	82.9	96.8	100.0
α at 65°	—	28.7	—	39.1	54.4	72.7	87.4	100.0

S. Arrhenius, S. Labendzinsky, H. Wolf, W. Hallwachs, G. N. Lewis and G. A. Linhart, and H. C. Jones and A. P. West also studied the ionization of zinc sulphate

soln. H. C. Jones and F. H. Getman obtained for a mol of CdSO_4 in v litres of water :

v	.	.	0.80	1.00	1.14	1.60	2.00	4.00	8.00	16.00
α	.	.	14.8	19.6	22.8	23.9	27.9	34.0	40.8	48.6

M. Chanoz, P. Godlewsky, G. N. Lewis and G. A. Linhart,²² and S. Labendzinsky also investigated the ionization of soln. of cadmium sulphate.

The **electromotive force** in millivolts between two soln. of zinc sulphate $\text{Zn} | m\text{ZnSO}_4, n\text{ZnSO}_4 | \text{Zn}$ with the percentage concentrations m and n , was found by J. Moser to be :

$n \rightarrow$.	.	15	30	45	60
$m \left\{ \begin{array}{l} 1 \\ 15 \\ 30 \\ 45 \end{array} \right.$.	.	18	22	28	36
	.	.	—	5	13	21
	.	.	—	—	7	17
	.	.	—	—	—	9

C. R. A. Wright and C. Thompson made similar determinations mainly with more dil. soln. of zinc sulphate ; E. Paschen, and A. Smits also worked on this subject. V. Karpen studied the e.m.f. of a cell with zinc : aq. soln. amyl alcohol : ZnSO_4 . J. Mathieu, M. Chanoz, and C. R. A. Wright and C. Thompson studied the e.m.f. between soln. of cadmium sulphate of different conc. S. Labendzinsky studied the e.m.f. of zinc in aq. soln. of sulphate against a normal calomel electrode, and the effect of temp. was investigated by K. A. Brander, A. Ebeling, E. Bouty, A. Gockel, A. Hagenbach, J. Gill, H. L. Bagard, and H. Jahn. R. Ramsey, and R. Gans investigated the effect of press. ; and H. Jahn the heat of absorption at the anode during electrolysis. B. Neumann, and A. Gockel investigated the e.m.f. of cadmium in soln. of cadmium sulphate. The thermodynamics of *Daniell's cell*, $\text{Zn} : \text{ZnSO}_4, \text{CuSO}_4 : \text{Cu}$, has been studied by W. Nernst, and by E. Cohen and co-workers ; E. Paschen found the e.m.f. decreases continuously with increasing conc. of the zinc sulphate soln. ; E. Cohen measured the internal resistance of Daniell's cell which fell from 420.2 ohms at 48° to 347.2 ohms at 64°—W. H. Preece's and H. S. Carhardt's data are inaccurate ; W. Block also found the temp. coeff. of the cell. H. S. Carhardt found the e.m.f. of *Clark's cell*, $\text{Zn}_{\text{amalgam}} \text{ZnSO}_4 | \text{ZnSO}_4, \text{Hg}_2\text{SO}_4 | \text{Hg}$, changed with the conc. of the soln.

Sp. gr. at 20°	.	.	1.036	1.036	1.096	1.206	1.293	1.383	1.429
E.m.f.	.	.	1.4850	1.4777	1.4724	1.4605	1.4540	1.4444	1.4380

The effect of temp. and conc. was also studied by G. Platner, and by H. T. Barnes and co-workers. The e.m.f. at θ° , according to W. Jäger and K. Kahle, is $1.4328 - 0.00119(\theta - 15) - 0.000007(\theta - 15)^2$ between 0° and 30° ; and, according to H. L. Callendar and H. T. Barnes, between 15° and 39°, the e.m.f. at θ° less the e.m.f. at 15° is $0.001200(\theta - 15) - 0.0000062(\theta - 15)^2 - 0.00006(\theta - 15)^3$. L. Clark gave 1.4378 for the e.m.f. of the cell at 15° ; R. T. Glazebrook and S. Skinner, 1.4344 ; K. Kahle, 1.4322 ; W. Jäger and K. Kahle, 1.4328—1.4329, and H. S. Carhart and K. E. Guthe, 1.4333. The mean value is 1.4334. The e.m.f. of the cell at the transition point of hepta- to hexa-hydrated zinc sulphate is 1.4005. The cell $\text{Cd} | \text{CdSO}_4, \text{Hg}_2\text{SO}_4 | \text{Hg}$ was studied by S. Czapski in 1884, and employed with amalgamated cadmium by E. Weston as a standard cell in 1892, in place of Clark's standard cell. The variation of the e.m.f. of *Weston's cell* with temp. is such that at θ° the e.m.f. is $1.0186 - 0.000038(\theta - 20) - 0.00000065(\theta - 20)^2$. The cell has been investigated by G. A. Hulett, R. A. Lehfeldt, E. Cohen and co-workers, H. von Steinwehr, J. Henderson, etc. E. A. Wolff gave for the e.m.f., E , of Weston's normal element at θ° between 0° and 40° with 12.5 per cent. cadmium amalgam as negative pole, $E = E_{20} - 0.0000406(\theta - 20) - 0.00000095(\theta - 20)^2 + 0.00000001(\theta - 20)^3$. W. Jäger and R. Wachsmuth gave $E = E_{20} - 0.000038(\theta - 20) - 0.00000065(\theta - 20)^2$. The latter agrees better with E. Cohen and J. J. Wolters' observations. R. Ramsey has studied the effect of press. on the cell. Certain

irregularities in the Weston's cell have been attributed by P. Kohnstamm and E. Cohen to a change in the cadmium sulphate at 15° , but H. von Steinwehr could find no evidence of a transition point between 13.7° and 25° ; H. C. Bijl attributed the irregularity to a change in the nature of the cadmium amalgam with a certain conc. of cadmium. J. Obata and Y. Ishibash studied the standard cadmium cells, and found that the acidity of the soln. had no influence on the temp. coeff.

E. Bouty, and A. Hagenbach measured the **thermoelectric force** of cadmium against cadmium sulphate. Heptahydrated zinc sulphate was found by M. Faraday,²³ and G. Meslin to be diamagnetic; J. Grailich and V. von Lang said it is strongly diamagnetic, and J. Plücker, feebly diamagnetic. H. Knoblauch and J. Tyndall studied the magnetic orientation of the crystals. G. Quincke found the **magnetic susceptibility** of aq. soln. of zinc sulphate, when that of a vacuum is zero, to be -0.27×10^{-6} units between 18° and 20° ; G. Meslin gave -0.53×10^{-6} units. G. Quincke also found the diamagnetization constant of soln. of sp. gr. 1.4393 to be -4.701×10^{-10} ; and the atomic magnetism, -0.0623×10^{-10} .

The aq. soln. of zinc and cadmium sulphates are feebly hydrolyzed when the soln. of these sulphates are tested with *herapathite*, i.e. quinine sulphatoperiodide. M. C. Lea²⁴ found no free sulphuric acid, and he attributed the reddening of litmus to a diminution in the dissociation of the litmus salt. J. A. Hedvall and J. Heuberger studied the reaction between zinc sulphate and magnesia or the alkaline earths.

J. H. Long measured the **hydrolysis** of soln. of zinc sulphate from the action of the salt on cane sugar; S. E. Moody from the action of potassium iodide and iodate; and H. G. Denham from measurements of the conc. of the H^+ -ions. The last-named showed that a state of equilibrium is assumed very slowly, and requires almost a month; as a result, the change in the degree of hydrolysis with a rise of temp. is not reversed directly on cooling, so that a state of *superhydrolysis* appears. H. Ley calculated the hydrolysis of a $\frac{1}{16}$ molar soln. to be 0.03 per cent.; and G. Carrara and G. B. Vespignani found 0.0075 per cent. for a $\frac{1}{2}$ molar soln. of zinc sulphate, and 0.017 per cent. for a 0.1N-soln. of cadmium sulphate. A. Colson studied the activity of aq. soln. of zinc sulphate; and he inferred that the salt has the formula $(ZnSO_4)_2$, and in aq. soln., the formula $HSO_4 \cdot Zn \cdot O \cdot Zn \cdot HSO_4$. A number of **basic zinc sulphates** has been reported, but there is little evidence to show that any of these are chemical individuals. Similar remarks apply to the so-called **basic cadmium sulphates**. V. Hassreidter,²⁵ and H. Pommerenke stated that basic zinc sulphate is formed during the roasting of zinc blende; and A. J. J. van de Velde and C. E. Wastels by the action of zinc on a soln. of cupric sulphate. F. O. Doeltz and C. A. Graumann claims that the alleged basic sulphates appear to be nothing more than mixtures of zinc oxide and zinc sulphate.

According to R. Schindler, a soln. of **zinc monoxysulphate**, $2ZnO \cdot SO_3$ or $ZnSO_4 \cdot ZnO$, is obtained when a conc. soln. of the sulphate is left for a long time in contact with metallic zinc or zinc oxide; and also by precipitating the oxide from half of a conc. soln. of the sulphate, and mixing the precipitate with the other half of the soln. The soln. yields small crystals on evaporation; the salt is decomposed by rapid boiling, slow evaporation, or by digestion with a large proportion of water, and zinc trioxysulphate is precipitated; and it gives a precipitate with tincture of galls. According to M. Athanasesco, small colourless transparent crystals of the monohydrate, $2ZnO \cdot SO_3 \cdot H_2O$, or $(ZnOH)_2SO_4$, are obtained by heating to 200° – 250° , in a sealed tube, a mixture of 3 parts of $ZnSO_4$ with 100 of water.

A. Vogel prepared dihydrated **zinc trioxysulphate**, $ZnSO_4 \cdot 3ZnO \cdot 2H_2O$, by heating zinc sulphate, until it is partially decomposed, and then boiling the residue with water; by boiling an aq. soln. of zinc sulphate with metallic zinc or zinc oxide; and by precipitating a conc. soln. of zinc sulphate with a small proportion of potassium hydroxide, and boiling the washed precipitate with water. According to O. B. Kühn, if too much alkali be used, a more basic salt will be formed. In all

cases the soln. is filtered hot, and the salt separates as the soln. cools. R. Schindler prepared this salt as indicated above. The opaque scales (A. Vogel) or four-sided needles (R. Schindler) lose water between 100° and 125° without melting or crumbling to pieces, and at a low red heat, the salt is decomposed and the zinc sulphate can be leached out with water. According to O. B. Kühn, the salt is sparingly soluble in hot or cold water, but soluble in a boiling soln. of zinc sulphate. If the material be dried at ordinary temp., R. Schindler's analysis corresponds with the *decahydrate* $\text{ZnSO}_4 \cdot 3\text{ZnO} \cdot 10\text{H}_2\text{O}$; and if dried at 100° , with the *dihydrate* $\text{ZnSO}_4 \cdot 3\text{ZnO} \cdot 2\text{H}_2\text{O}$; O. B. Kühn's and T. Graham's analyses correspond respectively with $4\text{H}_2\text{O}$ and $8\text{H}_2\text{O}$. S. J. Thugutt claimed to have made needle-like crystals of the *trihydrate*, corresponding with hydromagnesite in composition, by heating for 31 hrs. at 192° – 218° a mixture of 21 grms. of heptahydrated zinc sulphate, 3 grms. of sodium hydroxide, and 30 c.c. of water. A. Werner represents the formula:

W. Zubkowskaja claimed this salt to be a true chemical individual. F. Reindel, and J. Habermann made the *pentahydrate* by dropping dil. ammonia into a boiling conc. soln. of zinc sulphate. The white crystalline powder loses a part of the water at 100° and the rest at a higher temp. K. Kraut reported the *hexahydrate* is formed by pouring a soln. of sodium carbonate into an eq. amount of zinc sulphate in soln.; and M. Athanasesco, the *heptahydrate*, in hexagonal plates, by heating in a sealed tube at 160° a 25 per cent. soln. of zinc sulphate mixed with zinc oxide. F. Reindel made the *octohydrate* by boiling an excess of a soln. of zinc sulphate with ammonia; and K. Kraut, by boiling zinc oxide with a soln. of zinc sulphate. According to K. Kraut, the hydrate loses up to 12.47 per cent. of water over sulphuric acid; at 100° in a current of dry air, 18.5 per cent.; at 200° , 16.62 per cent.; and at 260° , 23.79 per cent. According to F. Reindel, it decomposes slowly in contact with water, and precipitates basic cupric sulphate from a soln. of cupric sulphate. When the octohydrate is heated with boiling water for six weeks, F. Reindel obtained what he regarded as **zinc heptoxydisulphate**, $9\text{ZnO} \cdot 2\text{SO}_3 \cdot 12\text{H}_2\text{O}$, or $2\text{ZnSO}_4 \cdot 7\text{ZnO} \cdot 12\text{H}_2\text{O}$, which loses 8.08 per cent. of water at 110° , and 18.43 per cent. at 260° .

S. U. Pickering reported the formation of a hydrated **zinc tetroxysulphate**, $\text{ZnSO}_4 \cdot 4\text{ZnO} \cdot n\text{H}_2\text{O}$, by treating a soln. of a mol of ZnSO_4 in 100 litres of water with the necessary amount of sodium carbonate; and S. E. Moody prepared the tetrahydrate by the incomplete hydrolysis of a soln. of zinc sulphate with potassium iodide and iodate. R. J. Kane claimed that when zinc diamminosulphate, $\text{ZnSO}_4 \cdot 2\text{NH}_3 \cdot \text{H}_2\text{O}$, or $\text{ZnSO}_4 \cdot 2\text{NH}_3$, is treated with water, decahydrated **zinc pentoxysulphate**, $6\text{ZnO} \cdot \text{SO}_3 \cdot 10\text{H}_2\text{O}$, or $\text{ZnSO}_4 \cdot 5\text{ZnO} \cdot 10\text{H}_2\text{O}$, is formed as a white powder. R. Schindler obtained what he regarded as dihydrated **zinc heptoxysulphate**, $8\text{ZnO} \cdot \text{SO}_3 \cdot 2\text{H}_2\text{O}$, or $\text{ZnSO}_4 \cdot 7\text{ZnO} \cdot 2\text{H}_2\text{O}$, by adding water to a conc. soln. of the monoxysulphate. The dried precipitate does not absorb carbon dioxide from air; when kept in a soln. of normal zinc sulphate it forms the trioxysulphate; and it is decomposed by gentle ignition into a mass from which water extracts zinc sulphate.

F. Stromeyer²⁶ prepared what is regarded as hydrated **cadmium monoxysulphate**, $\text{CdSO}_4 \cdot \text{CdO} \cdot \text{H}_2\text{O}$, by the ignition of monohydrated cadmium sulphate; O. B. Kühn by treating one-third of a soln. of cadmium sulphate with potassium hydroxide, and boiling the precipitate with the remaining two-thirds; J. Habermann, by dropping aq. ammonia into an aq. soln. of cadmium sulphate; B. Grützner, by warming a dil. soln. of cadmium sulphate with hexamethylene-tetramine; and M. Athanasesco, by heating 3 parts of cadmium sulphate with 100 parts of water in a sealed tube at 200° – 250° . The last-named process furnishes small colourless monoclinic or triclinic needle-like crystals. The product is sparingly soluble in water, and separates from that soln. in scaly crystals. S. U. Pickering made what he regarded as $4\text{CdO} \cdot \text{SO}_3 \cdot n\text{H}_2\text{O}$, that is, **cadmium trioxysulphate**, $\text{CdSO}_4 \cdot 3\text{CdO} \cdot n\text{H}_2\text{O}$, by adding a small proportion of sodium carbonate to a soln. of cadmium sulphate.

According to J. A. Arfvedson,²⁷ anhydrous zinc sulphate is reduced when heated in a current of **hydrogen**, forming zinc oxysulphide. E. Schüler found that anhydrous cadmium sulphate is reduced to cadmium, and cadmium sulphide, but no oxysulphide is formed. P. Klobb found anhydrous zinc sulphate is slowly dissolved by cold **water**, and rapidly by hot water. The solubility of zinc and cadmium sulphates in water has been previously discussed. T. Graham found the anhydrous salt unites with water with the development of heat—*vide* heat of soln.—and R. Brandes, and H. V. Blücher noted that when exposed to air, a mol of the sulphate absorbs nearly seven mols of water. For the hydrolytic action of water on zinc and cadmium sulphates, *vide supra*. G. J. Mulder stated that a sat. soln. of zinc sulphate is partially decomposed by water at about 40°; and above this temp., when an excess of the solid salt is present, a basic salt is precipitated, and the soln. becomes acidic.

An interesting experiment illustrating the increased hydrolysis which occurs with temp. is due to A. Gunn. Aq. ammonia (sp. gr. 0.88) is added drop by drop to a soln. of 0.2 grm. of zinc sulphate in 5 c.c. of water until two drops above that required to redissolve the precipitate have been added; 10–12 drops of 10 per cent. sodium phosphate soln. and 5 c.c. of water are added. This soln. is clear; it becomes opaque if a test-tube containing the liquid be heated to 100°; and it becomes clear on cooling. The effects can be reproduced a number of times until the loss of ammonia prevents the clearing of the turbid precipitate.

At 18°, 0.65 grm. of anhydrous zinc sulphate was found by C. A. L. de Bruyn to be dissolved by 100 grms. of absolute **methyl alcohol**, and 59 grms. of heptahydrated zinc sulphate; 100 grms. of 50 per cent. methyl alcohol dissolve 15.7 grms. of the heptahydrate at 16°, and 5.5 grms. at 0°. V. Augur found that methyl alcohol is decomposed, forming a little basic sulphate. H. Schiff found that 10, 20, and 40 per cent. **ethyl alcohol** dissolves respectively 51.1, 39, and 3.45 per cent. of heptahydrated zinc sulphate. R. Luther also found cadmium sulphate is soluble in methyl and ethyl alcohols; while A. Neumann found it to be insoluble in **ethyl acetate**. According to A. M. Ossendowsky, and M. Klever, 100 grms. of **glycerol** dissolve 35 grms. of zinc sulphate at 15.5°. According to O. Aschan, 100 grms. of 95 per cent. **formic acid** dissolve 0.06 grm. of cadmium sulphate at 18.5°. M. C. Schuyten found that an aq. soln. of zinc sulphate gives a precipitate when treated with **chlorine**; and with **bromine** or **iodine**, a substitution occurs. R. J. Kane stated that anhydrous zinc sulphate is dissolved but not decomposed by **hydrochloric acid**; but C. Hensgen found **hydrogen chloride** decomposes zinc sulphate at 225° to 250°. A. B. Prescott found that when a gram of zinc or cadmium sulphate is evaporated to dryness with 4.035 grms. of hydrochloric acid containing 1.251 grms. of HCl, respectively 4.007 and 0.017 grm. of chloride are formed. C. Baskerville found that cadmium sulphate when heated to 150° in a stream of hydrogen chloride furnishes a product with the composition $3\text{CdSO}_4 \cdot 4\text{H}_2\text{O} \cdot 4\text{HCl}$; at 200°, $2\text{CdSO}_4 \cdot 8\text{HCl}$; and with a more prolonged action at 200°, or with a shorter heating at a higher temp., cadmium chloride is formed. The **cadmium sulphate hydrochlorides** are very deliquescent.

L. N. Vauquelin,²⁸ and J. L. Gay Lussac found that when a mixture of zinc sulphate and **sulphur** is heated to redness in an earthen retort, sulphur dioxide is evolved, and a mixture of zinc sulphide and sulphate remains; and H. Rose found that zinc sulphate is converted into sulphide when heated with sulphur in a stream of hydrogen. According to G. Vortmann and C. Padberg, soln. of zinc and cadmium sulphates are not altered when boiled with sulphur; but K. Brückner found that zinc sulphate is converted into the sulphide with the evolution of sulphur dioxide, when the salt is triturated with sulphur. F. von Kobell obtained by chance monoclinic crystals of **zinc hydrosulphate**, $\text{ZnH}_2(\text{SO}_4)_2 \cdot 8\text{H}_2\text{O}$, or $\text{ZnSO}_4 \cdot \text{H}_2\text{SO}_4 \cdot 8\text{H}_2\text{O}$, from a sulphuric acid soln. of zinc sulphate. The salt is sparingly soluble in cold water and readily soluble in hot water; it fuses when heated, giving off water and sulphuric acid. R. Engel measured the solubility of cadmium sulphate in sulphuric acid at 0°, and found in grams per 100 grms. of water:

H ₂ SO ₄ . . .	0	1.90	8.18	13.78	21.23	23.34	26.38	35.06
CdSO ₄ . . .	74.61	72.87	65.03	52.73	42.52	38.56	34.07	23.96
Sp. gr. . . .	1.609	1.591	1.545	1.476	1.435	1.421	1.407	1.379

F. Bergius reported some inaccurate data for the solubility of zinc sulphate in **sulphuric acid** at 25°; J. Kendall and A. W. Davidson measured the solubility, and found:

Per cent. ZnSO ₄ . . .	0.20	0.30	0.41	0.45	0.41	0.45	0.52	0.67
F.p.	28.4°	40.1°	46.4°	49.2°	66.4°	78.0°	94.8°	128.6°
Solid phases . . .	ZnSO ₄ ·nH ₂ SO ₄				ZnSO ₄ (?)			

When zinc or cadmium sulphate is heated in a sealed tube with **sodium thiosulphate**, J. T. Norton found sulphur and the metal sulphide are formed.

According to J. L. Gay Lussac, when zinc sulphate, mixed with **carbon**, is heated to dull redness, sulphur dioxide and carbon dioxide are evolved in the proportion 2 : 1 by vol., and a mixture of zinc oxide, and traces of the sulphide remain; and at a still higher temp. some zinc is formed. If the mixture of zinc sulphate and carbon be rapidly heated to whiteness in a porcelain retort, sulphur dioxide alone is evolved at first, then follows carbon monoxide with a little of the dioxide, and the residue is zinc sulphide. H. O. Hofman and co-workers found the speed of the reaction between zinc sulphate and carbon increases as the temp. rises from 400° to 528°, and at the latter temp., the sulphate begins to be directly converted into the sulphide. According to K. Stammer, **carbon monoxide** converts red-hot zinc sulphate into the oxide. A. Christoff found that a litre of a 2*N*-soln. of zinc sulphate at 15° and 720 mm. press., absorbs 0.072 grm. of **carbon dioxide**. G. Gore noted a rise of 0.41° in 3 mins. when 6.5 grms. of powdered and dry **silica** were added to 50 c.c. of a 10 per cent. soln. of zinc sulphate.

According to J. Matuschek, when a mixture of dry zinc sulphate and **sodium nitrite** is shaken, nitrous oxide is formed. E. P. Alvarez obtained a white precipitate by adding **sodium pernitrate** to a soln. of zinc or cadmium sulphate. When zinc sulphate is heated in a stream of **ammonia**, W. R. Hodgkinson and C. C. Trench obtained approximately mol. proportions of zinc oxide and sulphide. For the complex salts with ammonia, *vide infra*. If a soln. of zinc sulphate is treated with **cupric hydroxide**, and gradually heated, the colour suddenly changes from blue to bluish-green between 70° and 75°, and, after boiling a few minutes, the soln. contains no copper. According to A. Recoura, the precipitate is a complex, ZnSO₄·3CuO.aq. According to D. Vitali, cadmium hydroxide is formed when a soln. of cadmium sulphate is treated with **silver oxide**. K. Brückner reduced zinc sulphate by heating it with powdered **magnesium**, and found sulphur, sulphur dioxide, magnesia, and thiosulphate were formed. K. A. Hofmann and K. Höschele found that when fused with **magnesium chloride**, volatile zinc chloride is formed. C. Paal and C. Amberger studied the action of zinc sulphate on **fats**; E. Rimbach and O. Weber, and L. Kahlenberg and co-workers, on **sugar**; C. J. Levites, on **starch**; and A. Bömer, on **albumen**.

§ 17. The Ammino- and Complex Salts of Zinc and Cadmium Sulphates

H. Rose¹ found that anhydrous zinc sulphate rapidly absorbs ammonia gas, much heat is evolved, and the mass swells up and crumbles to a white powder which retains nearly 34 per cent. of ammonia, and corresponds with $\text{ZnSO}_4 \cdot 5\text{NH}_3$, **zinc pentammino-sulphate**. The product gives off ammonia when heated to redness, and gives a small sublimate of ammonium sulphate; the residue is no longer soluble in ammonia. The pentammino-salt dissolves in water with the partial precipitation of zinc hydroxide. H. Rose similarly prepared **cadmium hexammino-sulphate**, $\text{CdSO}_4 \cdot 6\text{NH}_3$, which is decomposed by water. F. Isambert measured the dissociation press. up to 100° , and he found at 48.5° , 368 mm.; at 51.5° , 4.39 mm.; and at 100° , 1374 mm. The break in the curve near 100° corresponds with **cadmium diammino-sulphate**, $\text{CdSO}_4 \cdot 2\text{NH}_3$; above 100° , the compound is completely decomposed. F. Ephraim gave 19° for the temp. of decomposition of **zinc hexammino-sulphate**.

According to A. Gunn, a soln. of zinc ammino-sulphate can be prepared by dissolving about 0.2 grm. of zinc sulphate in 5 c.c. of water; and adding aq. ammonia (sp. gr. 0.880), drop by drop, until two drops have been added in excess of that required to redissolve the precipitate; 10–12 drops of a 10 per cent. soln. of sodium phosphate are then added, and 5 c.c. of water. The soln. is quite clear, but, when heated, the liquid becomes opaque, and the turbidity increases as the temp. rises until a thick curdy precipitate falls. This result is due to the dissociation of the soluble ammino-sulphate. When the vessel containing precipitate and mother liquid is warmed, the precipitate is quickly dissolved leaving the soln. as clear as at first. The precipitation by heating and re-solution on cooling can be repeated many times if care be taken to prevent the loss of ammonia. The equilibrium conditions in soln. containing zinc sulphate, water, and ammonia have been studied by W. Zubkowskaja. S. Tschumanoff has measured the electrical conductivity of the soln.; and A. A. Blanchard the viscosity of the soln. W. Gaus found the vap. press. of $\text{N-NH}_4\text{OH}$ in 0.01N- ZnSO_4 soln. at 25° is lowered by 0.44 mm., and similarly with cadmium sulphate, 0.52 mm.; he inferred that the

soln. contains 3 or 4 mols of NH_3 per gram-atom of zinc; H. Euler also inferred that the complex cation $[\text{Zn}(\text{NH}_3)_4]_n$ is present in the soln.; and H. M. Dawson and J. McCrae also showed that in soln. containing a large excess of ammonia, 4 mols of ammonia are united with one mol of zinc sulphate. W. Herz has studied the equilibrium between soln. of cadmium sulphate and ammonia.

According to R. J. Kane, when ammonia is passed into a hot sat. soln. of zinc sulphate, until the precipitate is redissolved, flocculent granules of **monohydrated zinc diammino-sulphate**, $\text{ZnSO}_4 \cdot 2\text{NH}_3 \cdot \text{H}_2\text{O}$, are deposited as the soln. cools; and more of the same product is obtained by evaporating the soln. to dryness, or allowing it to stand in a warm place. A gummy mass with the same composition is obtained by heating hydrated zinc tetrammino-sulphate until it begins to melt; if fused for a longer time, it loses its water, and forms what is possibly **zinc diammino-sulphate**, $\text{ZnSO}_4 \cdot 2\text{NH}_3$. At a still higher temp. the whole of the ammonia is evolved. When treated with water, zinc tetrammino-sulphate and ammonium sulphate pass into soln., and decahydrated **zinc pentoxysulphate**, $\text{ZnSO}_4 \cdot 5\text{ZnO} \cdot 10\text{H}_2\text{O}$, remains undissolved. F. Ephraim gave 185° for the decomposition temp. of **zinc triammino-sulphate**.

G. André reported that when a current of ammonia gas is passed into a cooled soln. of zinc sulphate in aq. ammonia, the soln. becomes opalescent; and if the passage of the gas is discontinued at this point, the liquid separates into two layers. When agitated, the two layers form an emulsion, but they rapidly separate again on standing. If the passage of the ammonia gas is continued, the bulk of the lower layer increases, and deliquescent needles of **trihydrated zinc tetramminosulphate**, $\text{ZnSO}_4 \cdot 4\text{NH}_3 \cdot 3\text{H}_2\text{O}$, separate. If the lower layer is allowed to remain by itself, it usually does not crystallize, but in some cases large tabular crystals of the same composition as the needles are deposited. When the lower layer is agitated with alcohol, no mixing occurs, but slender needles gradually separate at the junction of the two liquids. If a mixture of crystals and the lower liquid is gently heated at about 20° , the crystals dissolve with evolution of ammonia, and an oily lower layer then separates and gradually increases in volume. At 28° all the crystals have disappeared, and at 36° the liquid becomes homogeneous. The upper layer has a sp. gr. of 0.953 at 8° , and contains 25.69 per cent. of ammonia, and 2.15 per cent. of zinc; the lower layer has a sp. gr. of 1.2714 at 8° , and contains 22.16 per cent. of ammonia, and 13.62 per cent. of zinc. The separation into two layers can be observed with strong aq. ammonia and an aq. soln. of zinc sulphate.

If the soln. employed in the preparation of hydrated zinc diammino-sulphate be evaporated at ordinary temp., R. J. Kane showed that transparent crystals of **tetrahydrated zinc tetrammino-sulphate**, $\text{ZnSO}_4 \cdot 4\text{NH}_3 \cdot 4\text{H}_2\text{O}$, are formed; and these become opaque, when dried in air, passing into **dihydrated zinc tetrammino-sulphate**, $\text{ZnSO}_4 \cdot 4\text{NH}_3 \cdot 2\text{H}_2\text{O}$; and when kept between 27° and 38° , another mol of water is evolved and the mass crumbles to a white powder. If kept for a while at 100° , water and ammonia are given off, and the diammino-sulphate is formed as indicated above. The crystals are soluble in water. According to G. Müller, when a sat. soln. of zinc sulphate and ammonia is treated with alcohol, a syrupy liquid is produced which, in time, deposits tetrahedral crystals of the dihydrated tetrammino-sulphate which lose ammonia when exposed to air; if the crystallization occurs during a winter's cold, the tetrahydrate is formed. F. Ephraim gave 98.5° for the decomposition temp. of zinc tetrammino-sulphate.

R. Schindler claimed to have made **tetrahydrated zinc tetrammino-trioxysulphate**, $\text{ZnSO}_4 \cdot 3\text{ZnO} \cdot 4\text{NH}_3 \cdot 4\text{H}_2\text{O}$, or $4\text{ZnO} \cdot \text{SO}_3 \cdot 4\text{NH}_3 \cdot 4\text{H}_2\text{O}$, by precipitation from a boiling soln. of zinc sulphate supersaturated with ammonia, and continuing the boiling until the liquid no longer smells of ammonia. R. Schindler further found that when alcohol is added to an ammoniacal soln. of zinc mono- or trioxysulphate, small crystals are precipitated in which the proportion of acid : ammonia is less the greater the dilution. A soln. of zinc sulphate is not rendered turbid by the addition of small proportions of water, but with larger proportions of water, the

precipitate of basic sulphate is granular, and with still larger proportions of water, the precipitate is gelatinous. An ammoniacal soln. of zinc sulphate, when exposed to air, deposits zinc tetroxysulphate, and a zinc aminosulphate remains in soln. G. Bonnet obtained a zinc aminoxysulphate with 2.42 per cent. of ammonia, 81.65 per cent. of zinc oxide, and 15.93 per cent. of sulphur trioxide, by diluting an ammoniacal soln. of zinc sulphate with water.

G. André, and H. L. Wells prepared **dihydrated cadmium tetrammino-sulphate**, $\text{CdSO}_4 \cdot 4\text{NH}_3 \cdot 2\text{H}_2\text{O}$, from an ammoniacal soln. of cadmium sulphate by evaporation; by pouring a layer of alcohol over the soln.; by passing ammonia into the well-cooled soln. F. J. Malaguti and M. Sarzeau obtained **tetrahydrated cadmium tetrammino-sulphate**, $\text{CdSO}_4 \cdot 4\text{NH}_3 \cdot 4\text{H}_2\text{O}$, by pouring alcohol into an ammoniacal soln. of cadmium sulphate. The yellow crystals are decomposed by water, and give off ammonia when exposed to air. G. Müller prepared short six-sided prisms by a similar process, but they contained $2\frac{1}{2}$ mols of water.

A soln. of eq. proportions of zinc and ammonium sulphates furnishes crystals of **hexahydrated ammonium zinc sulphate**, $\text{ZnSO}_4 \cdot (\text{NH}_4)_2\text{SO}_4 \cdot 6\text{H}_2\text{O}$. With a great excess of ammonium sulphate, R. Kempf² found the yield to be almost quantitative. The double salt was prepared by F. Tassaert, and J. I. Pierre, and the latter's analysis corresponded more closely with the assumption that the crystals are heptahydrated. J. Troeger and E. Ewers made the crystals by digesting freshly precipitated and well-washed zinc hydroxide in a soln. of ammonium sulphate, and evaporating to crystallization. F. Reindel also obtained fine crystals of the salt. G. Wulff studied the rate of soln., and the rate of growth of the crystals; and also the disturbing influence of concentration currents. The transparent, colourless crystals have, according to E. Mitscherlich, the same form as the corresponding ammonium magnesium sulphate. The monoclinic prisms were examined by F. von Kobell, A. Murmann and L. Rotter, J. C. G. de Marignac, and A. E. H. Tutton; and, according to the latter, they have the axial ratios $a : b : c = 0.7368 : 1 : 0.4997$, and $\beta = 106^\circ 51'$. N. I. Surgunoff found the etched crystals had the symmetry of holohedral forms of monoclinic crystals. H. de Sénarmont studied the optical properties of the crystals. The sp. gr. given by L. Playfair and J. P. Joule is 1.897; by H. Schiff, 1.910; by H. G. F. Schröder, by F. L. Perrot, 1.931; and by A. E. H. Tutton, 1.9308 at $20^\circ/4^\circ$. L. Playfair and J. P. Joule found the sp. gr. of the salt dehydrated without fusion to be 2.222; and H. G. F. Schröder, 2.273. A. Murmann and L. Rotter gave 209.5 for the mol. vol., and A. E. H. Tutton, 206.38. When heated, the double sulphate was found by F. Reindel to be converted into anhydrous zinc sulphate. The crystals of the salt have a positive double refraction, and A. E. H. Tutton's values for the three indices of refraction are:

	Li-line.	C-line.	Na-line.	Tl-line.	F-line.	G-line.
α . . .	1.4858	1.4862	1.4888	1.4914	1.4948	1.4992
β . . .	1.4900	1.4904	1.4930	1.4957	1.4990	1.5036
γ . . .	1.4963	1.4967	1.4994	1.5027	1.5056	1.5102

The raising of the temp. from 20° to 70° lowered these numbers between 0.0013 and 0.0019 unit. F. L. Perrot also obtained concordant values for these constants, and he gave for the refraction eq. 102.70–103.74. C. Borel's values for the dielectric constants are $k_1 = 7.56$, $k_2 = 6.62$, and $k_3 = 5.35$. E. Tobler found that 100 parts of water dissolve:

	0°	10°	13°	15°	20°	30°	45°	60°	75°	85°
$(\text{NH}_4)_2\text{Zn}(\text{SO}_4)_2$.	7.3	8.8	10.0	12.5	12.6	16.5	21.7	29.7	37.8	46.2

J. Locke found a litre of a sat. soln. at 25° has 140.8 grms. of salt. F. Reindel found the aq. soln. has an acid reaction. When treated with sodium persulphate, the nitrogen is oxidized to nitrate.

According to J. Troeger and E. Ewers, a neutral soln. of cadmium sulphate gives a precipitate of cadmium hydroxide when treated with aq. ammonia, but no precipitation occurs if a little ammonium sulphate be present. E. Mitscherlich

first prepared **hexahydrated ammonium cadmium sulphate**, $\text{CdSO}_4(\text{NH}_4)_2\text{SO}_4 \cdot 6\text{H}_2\text{O}$, by the spontaneous evaporation of a soln. of equi-molecular proportions of the component salts. H. Rose, and C. von Hauer obtained the double salt in a similar manner; H. Schiff crystallized the salt from hot soln.; and J. Troeger and E. Ewers prepared the crystals by digesting freshly precipitated and well-washed cadmium hydroxide in a soln. of ammonium sulphate, and evaporating to crystallization from the soln. acidified with sulphuric acid. G. André obtained crystals with the composition $\text{CdSO}_4 \cdot 3(\text{NH}_4)_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$ by the prolonged action of cadmium oxide on a soln. of ammonium sulphate; and H. L. Wells, $\text{CdSO}_4 \cdot 3(\text{NH}_4)_2\text{SO}_4$. According to C. F. Rammelsberg, hexahydrated ammonium zinc sulphate forms monoclinic prisms analogous with the corresponding potassium salt, and with axial ratios $a:b:c=0.7431:1:0.4945$, and $\beta=107^\circ 41'$. A. Murmann and L. Rotter measured the crystal constants. Large crystals are opaque, small ones transparent. H. Schiff found the sp. gr. to be 2.073. A. Murmann and L. Rotter found the mol. vol. to be 215.73. The crystals are stable in air, and effloresce when dried over sulphuric acid. The salt loses all its water of crystallization at 100° , and melts at a higher temp. and loses water and ammonium sulphate, and finally sulphuric acid, leaving behind basic cadmium sulphate. According to C. von Hauer, the salt can be crystallized from water without decomposition. J. Locke found a litre of water dissolves 735 grms. of the anhydrous salt at 25° . F. Rüdorff dialyzed soln. of the salt, and measured the f.p. of the soln.; H. C. Jones and B. P. Caldwell measured the lowering of the f.p. and the electrical conductivity of soln. of the salt.

No compounds of **lithium sulphate** with zinc or cadmium sulphate have been observed. C. F. Rammelsberg³ failed to make a double salt of lithium and zinc sulphates. According to G. Calcagni and D. Marotta, lithium and cadmium sulphates give a V-shaped fusion curve with a eutectic at 551° with 45 per cent. of the cadmium salt. T. Graham prepared **tetrahydrated sodium zinc sulphate**, $\text{Na}_2\text{SO}_4 \cdot \text{ZnSO}_4 \cdot 4\text{H}_2\text{O}$, by evaporating in vacuo over conc. sulphuric acid, a mixed soln. of zinc sulphate and sodium hydrosulphate, NaHSO_4 ; and J. Koppel, by melting together eq. proportions of the component salts at 25° . T. Graham stated that the double salt is not obtained from aq. soln. containing zinc and sodium sulphates, for the component salts separated independently from the complex in cold or warm weather. Similar results were obtained if either salt was in excess. Hence, added T. Graham, "sodium sulphate does not displace the saline water of zinc sulphate so easily as potassium sulphate does." On the other hand, C. J. B. Karsten stated that he obtained the double salt by crystallization from a soln. made by adding Glauber's salt to a sat. soln. of zinc sulphate, or zinc sulphate to a sat. soln. of Glauber's salt, or from a mixed soln. of sodium chloride and zinc sulphate. He added that if the mixture be strongly heated and suddenly cooled, the two salts crystallize out separately. C. Tomlinson, C. F. Bucholz, and J. Koppel also obtained the double salt from aq. soln. of the component salts. The last-named found that the temp. of formation is 8.7° , and the cryohydric temp. of a soln. of zinc and sodium sulphates is -8.3° . He also studied the conditions for the formation of the double salt in aq. soln. The double salt is the sole solid phase at 25° when 17.58 and 15.63 per cent. respectively of zinc and sodium sulphates are in soln., and at 40° , when 17.75 and 15.72 per cent. respectively of zinc and sodium sulphates are in soln. W. H. Miller found the monoclinic crystals have the axial ratios $a:b:c=1.344:1:1.422$, and $\beta=100^\circ 22'$. A. Scacchi also studied the crystals. T. Graham said that the double salt is decomposed when dissolved in water. The crystals are about as deliquescent as sodium nitrate in a damp atm. The salt loses its water of crystallization when heated, and fuses at a dull red heat without losing acid fumes, and solidifies when cooled to a white opaque mass.

G. Calcagni and D. Marotta found that the reactions between fused sodium and cadmium sulphates are very different from those reported by H. le Chatelier. The fusion curve shows that three compounds are formed: **trisodium cadmium sulphate**,

$3\text{Na}_2\text{SO}_4 \cdot \text{CdSO}_4$, melting at 351° ; **sodium cadmium sulphate**, $\text{Na}_2\text{SO}_4 \cdot \text{CdSO}_4$, melting at 551° , and having a transformation point at about 496° ; and **sodium tricadmium sulphate**, $\text{Na}_2\text{SO}_4 \cdot 3\text{CdSO}_4$, melting at 746° , and having a transformation point at about 456° . C. von Hauer prepared small crystals of **dihydrated sodium cadmium sulphate**, $\text{Na}_2\text{SO}_4 \cdot \text{CdSO}_4 \cdot 2\text{H}_2\text{O}$, by crystallization from conc. soln. in the presence of an excess of sulphuric acid. J. Koppel has studied the conditions of existence of this salt in aq. soln. The double salt is the sole solid phase under the following conditions: at 24° when 22.25 and 15.07 per cent. of cadmium and sodium sulphates are in soln.; and at 40° , when 22.89 and 15.65 per cent. of cadmium and sodium sulphates are in soln.

F. R. Mallet⁴ claimed to have prepared crystals of **potassium dizinc sulphate**, $\text{K}_2\text{SO}_4 \cdot 2\text{ZnSO}_4$, by fusing these proportions of the component salts; the cold mass crystallizes in tetrahedrons; fuses at a red heat, and the mass bloats on cooling; adsorbs moisture from the air, and then decomposes. E. Mitscherlich prepared **hexahydrated potassium zinc sulphate**, $\text{K}_2\text{SO}_4 \cdot \text{ZnSO}_4 \cdot 6\text{H}_2\text{O}$, in the same manner as the corresponding ammonium salt. According to J. I. Pierre's analysis, the salt has 7 mols of H_2O , but this is wrong. H. Gerhart studied the development of the crystals in acid and neutral soln. C. F. Rammelsberg, E. F. Teschemaker, A. Murmann and L. Rotter have published crystallographic measurements of the monoclinic prisms; A. E. H. Tutton gave for the axial ratios $a : b : c = 0.7413 : 1 : 0.5044$, and $\beta = 104^\circ 18'$. The crystals are isomorphous with the corresponding potassium magnesium sulphate. The sp. gr. was found by H. Kopp to be 2.153; by L. Playfair and J. P. Joule, 2.24034 at 4° ; by H. Schiff, 2.153; by H. G. F. Schröder, 2.241; by F. L. Perrot, 2.245 (15°); and by A. E. H. Tutton, 2.2458 at $20^\circ/4^\circ$. The sp. gr. of the dehydrated salt is given by L. Playfair and J. P. Joule as 2.816; and by H. G. F. Schröder, as ranging from 2.240 to 2.249 if not melted, and from 2.703 to 3.027 when melted and cooled. A. E. H. Tutton gave 196.16 for the mol. vol. I. Traube found a 10 per cent. soln. has the sp. gr. 1.0678 at 15° , and the specific cohesion 14.012. N. van der Wal, and J. M. van Bemmelen and P. H. B. Ingenhous studied the rate of diffusion of the soln. According to T. Graham, the hexahydrate loses 5 mols of water in vacuo at 25° , and the sixth mol at 121° ; J. I. Pierre said at 180° . F. M. Raoult studied the lowering of the f.p. of the soln. G. Bruni gave -1.0° for the cryohydric temp. of the mixture $\text{K}_2\text{Zn}(\text{SO}_4)_2 + \text{ZnSO}_4$; and -6.6° for the mixture $\text{K}_2\text{Zn}(\text{SO}_4)_2 + \text{K}_2\text{SO}_4$. J. P. Joule and L. Playfair gave 0.00824 for the coeff. of cubical expansion between 0° and 100° . H. Kopp gave 0.270 for the sp. ht. P. W. Bridgman found that up to press. of 12,000 kgms. per sq. cm., hexahydrated potassium zinc sulphate shows no signs of undergoing a polymeric change; nor does the anhydrous salt at press. up to 12,000 kgms. per sq. cm., and at room temp., but there is a sharp break in the volume-press. curve at higher temp. This is taken to correspond with the reversible decomposition of the salt. J. Thomsen gave 4.140 Cals. for the heat of formation from $\text{K}_2\text{SO}_4 + \text{ZnSO}_4$; for the heat of hydration, $\text{K}_2\text{Zn}(\text{SO}_4)_2 + \text{H}_2\text{O}$, 18.91 Cals. at 18° , and for the heat of soln. of $\text{K}_2\text{Zn}(\text{SO}_4)_2 \cdot n\text{H}_2\text{O}$:

n	0	1	2	3	4	5	6
Heat of soln.	7.909	4.055	0.446	-2.634	-5.010	-9.176	-11.900 Cals.

The crystals of hexahydrated potassium zinc sulphate have a positive double refraction, and A. E. H. Tutton gave for the three refractive indices:

	Li-line	C-line	Na-line	Tl-line	F-line	G-line
α	1.4748	1.4752	1.4775	1.4797	1.4826	1.4866
β	1.4805	1.4809	1.4833	1.4857	1.4889	1.4929
γ	1.4938	1.4942	1.4969	1.4994	1.5027	1.5067

and for a rise of temp. from 20° to 70° , the indices become smaller by about 0.0018. F. L. Perrot made some concordant observations on the indices of refraction. J. H. Gladstone and W. Hibbert found that the mol. refraction for the H_α -, H_β -,

and the Na-lines of a 8.41 per cent. soln. was respectively 95.95, 98.01, and 96.03; and for a 11.94 per cent. soln., respectively 95.77, 98.08, and 95.94. E. Bouty, and J. Trötsch measured the electrical conductivity of aq. soln. of the salt. C. Borel gave for the dielectric constant $k_2=6.42$.

C. F. Bucholz reported that one part of the salt dissolves in 5 parts of cold water; E. Tobler that 100 parts of water dissolve

Salt	0°	10°	15°	25°	36°	45°	50°	58°	65°	70°
	12.6	18.7	22.5	28.5	39.9	51.2	54.0	67.0	81.3	87.9

J. Locke found that a litre of water at 25° dissolves 131.9 grms. of the anhydrous salt.

G. Calcagni and D. Marotta made a thermal analysis of fused mixtures of cadmium and potassium sulphates, and noted the formation of two compounds, **potassium dicadmium sulphate**, $K_2SO_4 \cdot 2CdSO_4$, melting at 763°, and of **potassium tricadmium sulphate**, $K_2SO_4 \cdot 3CdSO_4$, melting at 813°. According to E. Mitscherlich, **hexahydrated potassium cadmium sulphate**, $K_2SO_4 \cdot CdSO_4 \cdot 6H_2O$, can be made; and C. von Hauer claimed to have made it, but with difficulty, by saturating a soln. of potassium hydrosulphate with cadmium carbonate, acidifying with sulphuric acid, and evaporating the soln. spontaneously. The salt cannot be obtained by cooling a hot soln., and it is liable to decompose in its own mother liquid with a change of temp. The crystals are said to be efflorescent, and H. Schiff gives 2.438 for their sp. gr. G. Wyruboff said that the salt may possibly be obtained by crystallization of the soln. below 0°. A. E. H. Tutton did not succeed in making the hexahydrate. By spontaneously evaporating a neutral soln. of the component salts, C. von Hauer obtained crystals of **hemitrihydrated potassium cadmium sulphate**, $K_2SO_4 \cdot CdSO_4 \cdot 1\frac{1}{2}H_2O$. According to G. Wyruboff, the crystals are formed in aq. soln. between 26° and 64°; by exposing the dihydrate in air; or by heating the tetrahydrate to 120°. According to J. A. Krenner, the monoclinic prisms have the axial ratios $a:b:c=0.9873:1:2.0246$, and $\beta=104^\circ 42'$. G. Wyruboff gives for the solubility per 100 grms. of water 42.50 at 26°; 42.80 at 31°; 43.45 at 40°; and 44.90 at 64°. G. Wyruboff made **dihydrated potassium cadmium sulphate**, $K_2SO_4 \cdot CdSO_4 \cdot 2H_2O$, by evaporating a soln. of the components between 16° and 40°, or by exposing the tetrahydrate to air. The plate-like crystals belong to the triclinic system and have axial ratios and angles $a:b:c=0.7967:1:0.4242$, and $\alpha=89^\circ 25'$; $\beta=109^\circ 22'$; and $\gamma=88^\circ 26'$. J. A. Krenner, O. Mügge, and C. von Hauer also prepared crystals which had a strong negative double refraction, and a feeble dispersion. The sp. gr. is 2.922 at 16°; and the mol. vol. 143. The crystals of the dihydrate lose water when exposed to air and pass into the hemitrihydrate. G. Wyruboff gave for the solubility in 100 parts of water, 42.89 at 16°; 46.82 at 31°; and 47.40 at 40°. G. Wyruboff obtained monoclinic plates of tetrahydrated potassium cadmium sulphate, $K_2SO_4 \cdot CdSO_4 \cdot 4H_2O$, by cooling a hot soln. of the component salts, or by evaporating the soln. between 0° and 16°. The axial ratios are $a:b:c=1.0894:1:1.2365$, and $\beta=102^\circ 59'$. The sp. gr. is 2.523. The crystals have a positive double refraction and a feeble dispersion. The crystals effloresce on exposure to air, forming the dihydrate. At 120°, the crystals lose $2\frac{1}{2}$ mols of water and the remainder at 160°, forming the anhydrous **potassium cadmium sulphate**, $K_2SO_4 \cdot CdSO_4$.

According to R. Bunsen and G. Kirchhoff, the sulphates of the magnesium family readily form double salts with cæsium and rubidium sulphates. A. E. H. Tutton, and F. L. Perrot prepared **hexahydrated rubidium zinc sulphate**, $Rb_2SO_4 \cdot ZnSO_4 \cdot 6H_2O$, and **hexahydrated cæsium zinc sulphate**, $Cs_2SO_4 \cdot ZnSO_4 \cdot 6H_2O$, in monoclinic prisms by evaporating a soln. of the component salts. A. E. H. Tutton's values for the axial ratios of the rubidium salt are $a:b:c=0.7373:1:0.5011$, and $\beta=105^\circ 53'$, and for the cæsium salt, $a:b:c=0.7274:1:0.4960$, and $\beta=107^\circ 1'$. F. L. Perrot made similar observations. The sp. gr. of the rubidium and cæsium salts, according to A. E. H. Tutton, are respectively 2.591 and 2.875; and, according to F. L. Perrot,

respectively 2.595 and 2.88. The double refraction of both salts is positive. A. E. H. Tutton found for the three indices of refraction of the rubidium salt :

	Li-line.	C-line.	Na-line.	Tl-line.	F-line.	G-line.
α . . .	1.4807	1.4811	1.4833	1.4857	1.4886	1.4929
β . . .	1.4856	1.4860	1.4884	1.4908	1.4938	1.4980
γ . . .	1.4947	1.4951	1.4975	1.5001	1.5033	1.5078

with a diminution of 0.0012 when the temp. rises from 20° to 70°. He also found for the caesium salt :

	Li-line.	C-line.	Na-line.	Tl-line.	F-line.	G-line.
α . . .	1.4994	1.4998	1.5022	1.5047	1.5079	1.5125
β . . .	1.5020	1.5024	1.5048	1.5073	1.5104	1.5151
γ . . .	1.5064	1.5068	1.5093	1.5119	1.5152	1.5199

with a diminution of 0.0016 when the temp. rises from 20° to 70°. F. L. Perrot also made concordant observations on these two salts. J. Locke gives for the solubility of the anhydrous salt in a litre of water at 25°, 0.236 grm. of the rubidium salt, and 0.738 grm. for the caesium salt.

According to C. J. B. Karsten,⁵ **cupric sulphate** dissolves slowly in a sat. soln. of zinc sulphate ; but the latter dissolves rapidly in a sat. soln. of cupric sulphate ; and in both cases, the undissolved portion of the added salt is converted into a double salt. E. Mitscherlich found that a double salt crystallizes from a soln. containing an excess of zinc sulphate and the crystals have the form of ferrous sulphate with 7 mols of water of crystallization, while the crystals of the double salt obtained from a soln. containing an excess of cupric sulphate resemble the latter and have 5 mols of water of crystallization. C. F. Rammelsberg stated that in order to get the last-named crystals, for each mol of $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$, at least 5 mols of $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ must be present—C. Weltzien stated 13 mols of $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$. C. von Hauer obtained what he regarded as a double salt $(\text{CuSO}_4 \cdot 7\text{H}_2\text{O}) \cdot 2(\text{ZnSO}_4 \cdot 7\text{H}_2\text{O})$; J. Lefort, J. M. Thomson and W. P. Bloxam, and J. Nicklès, the double salt $(\text{CuSO}_4 \cdot 7\text{H}_2\text{O}) \cdot 3(\text{ZnSO}_4 \cdot 7\text{H}_2\text{O})$; and W. H. Wollaston, the double salt $(\text{CuSO}_4 \cdot 7\text{H}_2\text{O}) \cdot 4(\text{ZnSO}_4 \cdot 7\text{H}_2\text{O})$. The mixed crystals, $\text{CuSO}_4 \cdot 2\text{ZnSO}_4 \cdot 28\text{H}_2\text{O}$, obtained from the copper ores of Chessy, were called *vitriol mixte Chypre*. A. Scott also reported crystals of $\text{CuSO}_4 \cdot 2\text{ZnSO}_4 \cdot 3\text{H}_2\text{O}$ analogous with $\text{CuSO}_4 \cdot 2\text{FeSO}_4 \cdot 3\text{H}_2\text{O}$. The minerals *brochantite* of A. Levy ; *brongniartine* of J. J. N. Huot ; *krisurigit* of G. Forchhammer ; and *warringtonite* of N. S. Maskelyne, are more or less impure mixed crystals of zinc and copper sulphates ; they were also analyzed by G. Magnus, P. Berthier, H. Risse, F. Pisani, R. Warrington, G. Tschermak, F. von Kobell, F. Field, J. Domeyko, F. A. Genth, etc. P. A. Favre and C. A. Valson measured the heat developed during the soln. of the mixed crystals in water. E. S. Larsen and M. L. Glenn discussed the *melanterites*, $(\text{Zn}, \text{Cu}, \text{Fe})\text{SO}_4 \cdot 7\text{H}_2\text{O}$; and the *chalcantites*, $(\text{Zn}, \text{Cu})\text{SO}_4 \cdot 5\text{H}_2\text{O}$

J. W. Retgers found that with soln. of zinc and copper sulphates, rhombic mixed crystals resembling $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$ are produced with up to 2.32 per cent. $\text{CuSO}_4 \cdot 7\text{H}_2\text{O}$; monoclinic mixed crystals with 16.65 to 34.41 per cent. $\text{CuSO}_4 \cdot 7\text{H}_2\text{O}$; and triclinic mixed crystals with 16.65 to 34.41 per cent. $\text{CuSO}_4 \cdot 7\text{H}_2\text{O}$; and triclinic mixed crystals with 92.02 to 100 per cent. $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$. The composition of the mixed crystals of one salt with a maximum of the other—*mixing limit*—was shown by H. W. Foote to be a function of the temp. The two salts do not form completely isomorphous crystals between 12° and 56° ; and in soln. yielding two forms of mixed crystals, the proportion of copper sulphate in soln. remains nearly constant, while the proportion of zinc sulphate increases considerably with rise of temp. The subject has also been investigated by R. Hollmann, E. Cohen, W. Stortenbeker, and L. de Boisbaudran—*vide* cupric sulphate. J. W. Retgers believed that no double compound of zinc and copper sulphates has been prepared, but R. Hollmann inferred that the existence of maxima in the vap. press. curves of soln. of the mixed salts corresponds with the existence of soln. of definite double

compounds. A. Étard obtained rose-coloured crystals of a *cupric zinc hydrosulphate*, $2(\text{ZnSO}_4 \cdot \text{CuSO}_4) \cdot \text{H}_2\text{SO}_4$, by heating to 200° a soln. of the constituents in the smallest possible proportion of water, and in large excess of conc. sulphuric acid. Mixed crystals of *triple salts* with zinc, cupric, and ammonium sulphates were studied by H. Vohl, and A. Fock; and mixed crystals of zinc, cupric, and potassium sulphates by A. Bette, and H. Vohl. Mixed crystals of cupric and cadmium sulphates were found by J. W. Retgers to be colourless and monoclinic with 99.45 to 100 per cent. of $\text{CdSO}_4 \cdot 3\text{H}_2\text{O}$; and blue and triclinic with 98.29 to 100 per cent. of $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$.

Several **basic cupric zinc sulphates** have been reported. The mineral *serpierite* occurs in rhombic crystals at Laurium, and was described by A. des Cloizeaux,⁶ and E. Bertrand; *cuprogolarite* occurs as a greenish-blue incrustation on the walls of an abandoned zinc mine at Galena (Cherokee, Kansas) and was described by A. F. Rogers. A. Recoura described as compounds $7\text{ZnSO}_4 \cdot 24\text{CuO} \cdot n\text{H}_2\text{O}$, and $\text{ZnSO}_4 \cdot 3\text{CuO} \cdot \text{H}_2\text{O}$; A. Mailhe, $\text{ZnSO}_4 \cdot 3\text{CuO} \cdot 5\text{H}_2\text{O}$, $\text{ZnSO}_4 \cdot 5\text{H}_2\text{O}$, $2\text{ZnSO}_4 \cdot 3\text{CuO} \cdot 12\text{H}_2\text{O}$, and $3\text{ZnO} \cdot 2\text{CuSO}_4 \cdot 12\text{H}_2\text{O}$; and A. Larsen, $2\text{ZnO} \cdot \text{CuSO}_4 \cdot 21\text{H}_2\text{O}$. A. Recoura also described **basic cupric cadmium sulphates**, $6\text{CdSO}_4 \cdot 20\text{CuO} \cdot n\text{H}_2\text{O}$, and $\text{CdSO}_4 \cdot 3\text{CuO} \cdot n\text{H}_2\text{O}$; and A. Mailhe, $2\text{CdSO}_4 \cdot 3\text{CuO} \cdot 8\text{H}_2\text{O}$, and $2\text{CdSO}_4 \cdot 3\text{CuO} \cdot 12\text{H}_2\text{O}$.

J. d'Ans⁷ boiled a conc. soln. of potassium and zinc sulphates with calcium sulphate, and rapidly washed the product with a little water, dil. alcohol, and a mixture of alcohol and ether. The dried product had a composition, **dihydrated potassium dicalcium zinc sulphate**, $\text{K}_2\text{Ca}_2\text{Zn}(\text{SO}_4)_4 \cdot 2\text{H}_2\text{O}$, and he regarded it as a *potassium-zinc-polyhalite*. He likewise prepared **dihydrated potassium dicalcium cadmium sulphate**, $\text{K}_2\text{Ca}_2\text{Cd}(\text{SO}_4)_4 \cdot 2\text{H}_2\text{O}$, or *potassium-cadmium-polyhalite*. According to G. Klatzo, monoclinic prisms of **beryllium zinc sulphate**, $2\text{BeSO}_4 \cdot 3\text{ZnSO}_4 \cdot 35\text{H}_2\text{O}$, isomorphous with heptahydrated zinc sulphate, are obtained by crystallization from a conc. soln. of the component salts.

C. J. B. Karsten⁸ found zinc sulphate and **magnesium sulphate** crystallize together. W. Stortenbeker found the solubility isotherm shows a continuous isomorphous series. R. Hollmann assumed that double sulphates are formed, but E. Barchet believed that this is not the case. As E. Sommerfeld showed, the question at issue depends on the definition of a chemical individual. H. Dufet, and G. Wyruboff found the variation in the sp. gr., and prism angle (110) : (110) of mixtures of zinc and magnesium sulphates to be :

MgSO ₄	.	100	78.88	74.44	62.70	57.59	42.80	35.64	18.11	0 %
Sp. gr.	.	1.6760	1.7359	1.7472	1.7816	1.7977	1.8415	1.8604	1.9094	1.9600
Angle	.	90° 35'	90° 42.5'	90° 45'	90° 49'	90° 52'	90° 56.5'	90° 59'	91° 06'	91° 12'

G. Bruni found the cryohydric temp. of mixtures of the two sulphates to be :

MgSO ₄	.	100	69.5	58.8	37.5	19.6	0 molar %
Cry. temp.	.	-5.2°	-5.5°	-5.5°	-6.0°	-6.2°	-6.4°

R. Hollmann gave for the vap. press. of mixtures :

ZnSO ₄	.	0	20.4	31.2	37.5	40.2	49.4	59.8	71.1	79.0	100 %
H ₂ SO ₄	.	45.14	46.09	46.60	43.20	44.17	43.31	40.93	41.50	41.04	38.61
Vap. press.	.	7.7	8.0	8.2	8.7	8.3	8.7	9.6	9.5	9.5	10.5

E. Barchet determined the relation between the relative proportions of $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$ and $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ in soln. and mixed crystals.

Mixed crystals	($\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$.	.	13.41	20.25	28.67	31.29	46.37	49.05	59.65
	$\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$.	.	86.59	79.59	71.33	68.71	53.63	50.95	40.35
Soln.	($\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$.	.	14.47	20.34	33.71	38.12	50.98	53.54	63.94
	$\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$.	.	85.53	79.56	76.29	61.88	49.02	46.46	36.06

The alleged magnesium zinc sulphates are : (i) $\text{ZnSO}_4 \cdot \text{MgSO}_4 \cdot 14\text{H}_2\text{O}$, prepared by J. I. Pierre, which retains 2 mols of its water of crystallization at 200° , but loses it at 250° – 260° . H. Schiff gave 1.817 for the sp. gr. R. Hollmann, E. Barchet, C. von Hauer, and M. Schaeuffele have worked on this compound.

(ii) $3\text{ZnSO}_4 \cdot 5\text{MgSO}_4 \cdot 14\text{H}_2\text{O}$ was also prepared by H. Schiff, who gave 1.770 for the sp. gr. (iii) $\text{ZnSO}_4 \cdot 2\text{MgSO}_4 \cdot 21\text{H}_2\text{O}$ was prepared by R. Hollmann, and M. Schaeuffele, but E. Barchet denied its existence. H. Schiff also reported **magnesium cadmium sulphate**, $\text{CdSO}_4 \cdot \text{MgSO}_4 \cdot 14\text{H}_2\text{O}$, to be formed by evaporating a sulphuric acid soln. of magnesium and cadmium carbonates in eq. proportions. The sp. gr. of the four-sided prisms is 1.982. The salt dried over sulphuric acid has the composition $\text{CdSO}_4 \cdot \text{MgSO}_4 \cdot 6\text{H}_2\text{O}$. A. Bette prepared *triple salts* of zinc and magnesium sulphates with ammonium or potassium sulphate. H. Vohl prepared **potassium magnesium zinc sulphate**, $2\text{K}_2\text{SO}_4 \cdot \text{ZnSO}_4 \cdot \text{MgSO}_4 \cdot 12\text{H}_2\text{O}$ and **potassium ammonium magnesium sulphate**, with $(\text{NH}_4)_2$ substituted in place of K_2 . H. Schiff reported *hydrated triple salts*, **ammonium potassium zinc sulphates**, with $(\text{NH}_4)_2\text{SO}_4 : \text{K}_2\text{SO}_4 : \text{ZnSO}_4 : \text{H}_2\text{O}$ in the mol. proportions 2 : 3 : 2 : 3 ; 1 : 2 : 1 : 18 ; and 1 : 1 : 1 : 12.

§ 18. Zinc and Cadmium Carbonates

The term *calamine*—or, in Germany *Galmey*—is supposed to be a corruption of Pliny's *cadmia*. G. Agricola¹ said that the term was derived from *calamus*, a reed, in allusion to the slender stalactitic forms common with *cadmia fornacum*. The *cadmia* of Pliny, and the early writers, included both the silicate and the carbonate, as well as the oxide from the flues of furnaces. The two ores were confounded under the term *lapis calaminaris*, *calamine*, or *galmei*. Some early analyses showed a difference in composition, thus, T. Bergmann showed that a sample from Holywell, which he called *zincum acido aëro mineralisatum*, contained 28 per cent. of carbon dioxide; M. H. Klaproth, that a sample from Derbyshire contained 33 per cent. of silica; and B. Pelletier, that a sample from Fribourg (Brisgau), which he called *zeolite of Brisgau*, contained 52 per cent. of silica. J. B. L. Romé de l'Isle distinguished between the crystalline forms of the two species, the one was described as occurring in prismatic crystals with dihedral summits, and the other as scalenohedral like dog's tooth spar, while R. J. Haüy regarded *zinc carbonatée* as an impure calcareous *zinc oxydé*. In 1803, J. Smithson established the difference between the two minerals and he denominated the silicate *electric calamine*, on account of its pyroelectric qualities. In 1807, A. Brongniart called the silicate *calamine*, and the carbonate *zinc carbonatée*; and in 1732, F. S. Beudant applied the term *smithsonite* to the carbonate. The two minerals were thus clearly distinguished and named. Confusion resulted when H. J. Brooke and W. H. Miller suggested reversing these terms, and when G. A. Kenngott proposed the term *hemimorphite* for the silicate. The carbonate is commonly called *calamine* or *zinc spar* by British mineralogists, and *smithsonite* by American; while the silicate is commonly called

hemimorphite or *electric calamine* by British mineralogists, and *calamine* by American.

Zinc carbonate occurs in nature as a crystallized botryoidal, stalactitic, granular, or earthy mass. Analyses have been published by J. Smithson,² E. Schmidt, W. Elderhorst, H. Risse, P. Berthier, F. von Kobell, M. Long, F. de Marigny, C. J. B. Karsten, F. A. Gent, E. Ludwig, R. Blum, N. Collie, J. A. Tanner, H. Traube, J. Loczka, L. G. Eakins and H. N. Stokes, W. Orloff, P. Argall, W. H. Miller, J. C. Brauner, C. H. Warren, A. Christomanos, G. Linder, C. F. Rammelsberg, F. Cornu, B. Neumann and E. Wittich, C. R. van Hise, etc. A ferruginous variety has been called *zinc-iron-spar*, or, according to A. Breithaupt, *capnite*, or *kapnite*; a cupriferous variety, *herrerite*; a ferruginous and manganiferous variety, *monheimite*; and a cadmiferous variety, *cadmium-zinc-spar*.

In his essay *De acido aëreo* (Upsala, 1774), T. Bergmann stated that zinc dissolves in carbonic acid, and it forms zinc carbonate. R. Schindler³ claimed to have made normal **zinc carbonate**, ZnCO_3 , containing a little water—probably owing to its association with a little hydrated basic zinc carbonate—by precipitating in the cold a soln. of zinc sulphate in ten times its weight of water with an equi-molar proportion of alkali hydrocarbonate. The white powder obtained by drying the washed precipitate was considered by H. Karmarsch, and by J. Lefort to be a basic carbonate. R. Schindler also obtained a granular powder, supposed to be the normal carbonate, by the spontaneous evaporation of a soln. of zinc, zinc hydroxide, or carbonate in carbonic acid. K. Kraut recommended adding a soln. of 140 grms. of potassium hydrocarbonate or of 117 grms. of sodium hydrocarbonate, sat. with carbon dioxide, to a soln. of 100 grms. of heptahydrated zinc sulphate, cooled to 3° or 4°; the precipitate was filtered by suction as rapidly as possible, washed with ice-cold water, and dried by press. H. de Sénarmont made normal zinc carbonate as a crystalline powder, by heating in a sealed tube to 150° an aq. soln. of zinc sulphate and sodium carbonate; or to 160°, an aq. soln. of a zinc salt and sodium hydrocarbonate. G. Rose employed a similar process. L. Bourgeois recommended heating to 100°, in a sealed tube, a mixture of zinc and carbonic acid. P. N. Raikow passed carbon dioxide into water with zinc hydroxide in suspension. A. Schmidt synthesized zinc-iron-spar by mixing precipitated calcium carbonate with a soln. of ferruginous zinc sulphate, and allowing the mixture to stand in the presence of free carbon dioxide. The crystals of gypsum were removed by washing with hot water. H. Rose added an excess of potassium (not sodium) hydrocarbonate to a cold soln. of zinc sulphate, and found that the product washed and dried at 200° had the composition $5\text{ZnCO}_3 \cdot \text{H}_2\text{O}$. H. St. C. Deville found that the precipitate obtained from soln. of zinc sulphate and ammonium hydrocarbonate, when allowed to stand with the mother liquid, forms a granular powder of **hemihydrated zinc carbonate**, $2\text{ZnCO}_3 \cdot \text{H}_2\text{O}$, which, according to H. Mikusch, is crystalline. A. Belar obtained fine crystals of **monohydrated zinc carbonate**, $\text{ZnCO}_3 \cdot \text{H}_2\text{O}$, by allowing soln. of zinc carbonate in ammonium carbonate to stand for three months. The presence of copper carbonate facilitates the crystallization. K. Kraut also made the same hydrate by the action of sodium hydrocarbonate on a soln. of a zinc salt.

F. Stromeyer,⁴ and J. F. John precipitated what they considered to be anhydrous **cadmium carbonate**, CdCO_3 , by adding an alkali carbonate to a soln. of a cadmium salt; but J. Lefort believed the precipitate to be **hemihydrated cadmium carbonate**, $\text{CdCO}_3 \cdot \frac{1}{2}\text{H}_2\text{O}$, which lost its water between 80° and 120°. K. Kraut made the hemihydrate by pouring a large excess of ammonium carbonate into a cold soln. of cadmium nitrate. According to H. Rose, cadmium oxide is more readily attacked than zinc oxide by carbon dioxide, and less readily attacked by water. The precipitate obtained by adding sodium carbonate to a soln. of a cadmium salt is washed with difficulty; the precipitate with potassium carbonate approximates closely to that of normal cadmium carbonate, especially if an excess of potassium carbonate is employed, but in every case some basic cadmium carbonate appears to be formed: with cold conc. soln. the precipitate has $\text{Cd}(\text{OH})_2 : \text{CdCO}_3 : \text{H}_2\text{O}$ in the proportion 1:10:2; with cold dil. soln., 1:10:3; with hot conc. soln.,

6:50:11; and with hot dil. soln., 9:50:12. A. de Schulten obtained crystals of the normal carbonate by washing with aq. ammonia the precipitate obtained by adding an excess of ammonium carbonate to a conc. soln. of cadmium chloride, and heating the diluted mixture on a water-bath; or, according to L. Bourgeois, by heating in a sealed tube the amorphous carbonate with ammonium chloride or nitrate and water at 150°–180°; or with urea at 140°. K. Kraut dropped a soln. of cadmium sulphate into an eq. soln. of sodium carbonate at the b.p., or boiling the precipitate with the mother liquid for an hour.

The **crystals** of zinc carbonate are scalenohedral and isomorphous with the trigonal family of calcites; according to A. Breithaupt,⁵ the axial ratio is $a:c = 1:0.8062$, and $\alpha = 105^\circ 28'$; similarly, cadmium carbonate was found by A. de Schulten to have the axial ratio $a:c = 1:0.8363$, and $\alpha = 102^\circ 30'$. A. Belar found monohydrated zinc carbonate forms bipyramids belonging to the rhombic system with $a:b:c = 0.8316:1:0.5994$. According to W. L. Bragg, the **X-radiogram** shows the distance apart of the atoms in zinc carbonate to be 1.99 Å., and of cadmium carbonate, 2.21 Å. Some observations on this subject were made by M. L. Huggins. The **specific gravity** of zinc carbonate, according to J. Smithson, is 4.339; W. Haidinger and W. H. Wollaston gave 4.42; A. Levy, 4.45; C. J. B. Karsten, 4.3765; and W. Orloff, 4.30–4.45—mol. vol. 28.51. The sp. gr. of cadmium carbonate was given as 4.42 at 17° by W. Herapath; 4.4938 by C. J. B. Karsten; 4.258 by H. G. F. Schröder; and 4.960 at 15° by A. de Schulten. The **hardness** of zinc carbonate is near that of apatite—5 on Mohs' scale. This subject was discussed by A. Reis and L. Zimmermann.

F. O. Doeltz and C. A. Graumann⁶ found that some carbon dioxide is given off when commercial zinc carbonate is heated to 90°; the **decomposition** is faster as the temp. rises; at 144°, the decomposition is rapid; at 300°, the decomposition is complete in an hour, and in half an hour at 400° or higher. F. O. Doeltz and C. A. Graumann found the decomposition of the native carbonate begins at 137°, and K. Friedrich found that the decomposition of zinc spar begins at 395°; siderite at 380°; magnesite at 570°; and calcspar at 895°; and that the decomposition of smithsonite is a maximum at 440°. G. Lindner found the **specific heat** of zinc carbonate is 0.1507 between 0° and 100°; 0.1608, between 0° and 200°; 0.1706 between 0° and 300°; and 0.1740 between 0° and 400°. He also found:

Sp. ht.	50°	100°	150°	200°	250°
	0.1507	0.1608	0.1706	0.1805	0.1902

so that the sp. ht. increases with rise of temp. and the increase is smaller the higher the temp. According to M. Berthelot, the **heat of formation** of precipitated zinc carbonate is (Zn, C, 3O)=194.2 Cals., and, according to J. Thomsen, (Cd, C, 3O)=181.9 Cals., or (Cd, O, CO₂)=84.93 Cals.

W. Orloff⁷ found the **double refraction** of native crystals of zinc carbonate, like that of other trigonal carbonates, is strongly negative, and the **index of refraction** $\epsilon = 1.61766$. E. Goldstein studied the **phosphorescence** of cadmium carbonate under the influence of cathode rays. G. F. Kunz and C. Baskerville found hydrozincite from Algiers gives a **fluorescence** when exposed to ultra-violet light. According to J. Perrin, the particles of zinc carbonate suspended in alkaline soln. are negative; in acid soln. they are positive; and in neutral water, they are electrically neutral. A. E. Garrett found the **electrical conductivity** did not rise when the carbonate is heated.

Zinc spar was found by F. Cornu⁸ to react distinctly alkaline to neutral litmus. J. von Essen found that a litre of water at 15° dissolves 0.01 grm. of zinc carbonate, and F. Ageno and E. Valla found at 25°, 1.64×10^{-4} mols or 0.206 grm. per litre. H. J. Smith estimated that if zinc carbonate were not hydrolyzed, its solubility in water at 25° would be 4.58×10^{-6} mols per litre. R. Fresenius said a litre of cold water dissolves 0.0224 grm. of basic zinc carbonate. R. Schindler found ignited zinc oxide does not absorb carbon dioxide from the atm., but H. W. F. Wackenroder

found that about 8.3 per cent. of carbon dioxide, is taken up if that gas be passed through water with zinc oxide in suspension. F. Jahn also showed that zinc carbonate, zinc hydroxide, and even metallic zinc, are easily soluble in an aq. soln. of carbon dioxide. C. A. Seyler showed that the solubility is a function of the dissolved carbon dioxide. Presumably **zinc hydrocarbonate**, $\text{Zn}(\text{HCO}_3)_2$, passes into soln. H. J. Smith showed that the solubility of zinc hydrocarbonate in carbonic acid, expressed in mols per litre when the press. of the carbon dioxide is expressed in atm. at 25° , is :

Press. CO_2	4.12	7.64	12.16	19.73	22.56	40.61
Mols H_2CO_3	0.1390	0.2579	0.4103	0.6657	0.7610	1.3701
Mols $\text{Zn}(\text{HCO}_3)_2$	0.00194	0.00242	0.00278	0.00317	0.00343	0.00445
α	0.909	0.899	0.894	0.888	0.885	0.871
$K \times 10^3$	3.40	3.41	3.35	3.22	3.33	3.48

where α represents the **degree of ionization** of the zinc hydrocarbonate such that $\alpha[\text{Zn}(\text{HCO}_3)_2] = \text{Fe}^{++}$. Since $[\text{Zn}^{++}][\text{CO}_3^{--}] = K_3$, the **solubility product**; and $[\text{H}^+][\text{HCO}_3^-] = K_1[\text{H}_2\text{CO}_3]$; and $[\text{H}^+][\text{CO}_3^{--}] = K_2[\text{HCO}_3^-]$,

$$\frac{\alpha[\text{Zn}(\text{HCO}_3)_2]}{\sqrt{[\text{H}_2\text{CO}_3]}} = \sqrt[3]{\frac{K_1 K_2}{4K_3}} = K$$

where K is the equilibrium constant for the system. The average value of the equilibrium constant, K , at 25° is 0.00336, and at 30° , 0.00347. From the known values $K = 3.36 \times 10^{-3}$; $K_1 = 3.50 \times 10^{-7}$; and $K_2 = 4.91 \times 10^{-11}$, it follows that the solubility product of zinc carbonate at 25° is $K_3 = 21 \times 10^{-12}$. C. Immerwahr obtained values for the solubilities of zinc and cadmium carbonates, and she studied the action of potassium carbonate on soln. of the chlorides.

J. von Essen found that the solubility of zinc carbonate is raised when *sodium chloride* or *potassium chloride* is also present, and the action of the alkali chlorides on zinc carbonate was studied by A. Cantoni and J. Passamanik. H. Ehlert found that a litre of a 5 per cent. soln. of sodium chloride dissolves 0.02273 gm. ZnCO_3 ; 10 per cent. soln., 0.04564 gm.; and a sat. soln., 0.13038 gm.; a litre of a 10 per cent. soln. of *sodium nitrate* dissolves 0.058981 gm. ZnCO_3 ; and a sat. soln., 0.1490 gm.; a litre of a 10 per cent. soln. of *sodium sulphate* dissolves 0.009313 gm. of ZnCO_3 ; and a litre of a sat. soln., 0.015521 gm. A small proportion of sodium sulphate thus depresses the solubility of zinc carbonate while a large proportion raises the solubility. A. Cantoni and J. Passamanik showed that the decomposition of zinc carbonate by alkali chlorides is small; it is larger with ammonium chloride, and with increasing temp. and conc. of the soln. W. O. de Coninck found a small reaction between a soln. of sodium chloride and zinc or cadmium carbonate in sunlight. A. Frebault and A. Destrem found zinc carbonate is decomposed by a soln. of *sodium phosphate*.

W. Eidmann found that zinc carbonate is insoluble in **acetone**; A. Naumann, that cadmium carbonate is insoluble in **ethyl acetate**; P. Sabatier, that zinc carbonate reacts with **nitrodisulphonic acid**, forming zinc sulphate; W. Ipatjeff, that zinc carbonate reacts with **acetic acid**, forming ketone, water, and carbon dioxide; and W. Löb studied the reaction with **formaldehyde**, etc. L. Naudin and F. de Montholon found that zinc carbonate is completely converted by **hydrogen sulphide** into zinc sulphide. M. Kohn noted that precipitated cadmium carbonate precipitates ferric salt soln. in the cold completely, while chromic, uranyl, and aluminium nitrates are but incompletely precipitated.

When zinc salts in soln. are precipitated by alkali carbonates, the products are unstable and of variable composition; and as a result, a large number of **basic zinc carbonates** have been reported. A sat. aq. soln. of potassium or ammonium carbonate gives a precipitate with zinc salts which is soluble in an excess of the precipitant, presumably, said C. Arnold,⁹ by forming a soluble basic zinc carbonate. H. Mikusch believed that only one basic carbonate exists as a stable chemical

individual, and that it is represented by $5\text{ZnO} \cdot 2\text{CO}_2 \cdot 4\text{H}_2\text{O}$; and he added that all the other reputed basic zinc carbonates are solid soln. of zinc hydroxide, and normal zinc carbonate. In H. Mikusch's experiments, neutral zinc carbonate was progressively hydrolyzed with water at 25° , 50° , and 100° , and the composition of the liquid and solid phases determined from time to time; conversely, zinc carbonate was formed by the progressive action of zinc hydroxide and carbonic acid, and the solid and liquid phases similarly treated. In all cases, sodium acetate was added to the soln. in order to dissolve sufficient carbonate and hydroxide to allow of analysis. Analyses of the massive or earthy mineral *hydrozincite*—and the varieties *zinc bloom*, *marionite*, *zinconite*, and *cagamite*—by J. Smithson; C. J. B. Karsten; C. Schnabel; T. Petersen and E. Voit; A. Terreil; W. K. Sullivan; G. Bonnet; A. Goebel; W. Elderhorst; C. F. Rammelsberg, G. Cesaro, A. Cossa, V. von Zepharovich, K. Kraut, and A. F. Rogers, show that the composition ranges between $\text{ZnCO}_3 \cdot 2\text{Zn}(\text{OH})_2 \cdot n\text{H}_2\text{O}$ and $3\text{ZnCO}_3 \cdot \text{Zn}(\text{OH})_2 \cdot 3\text{H}_2\text{O}$. C. Perrier showed that zinc carbonate is also associated with the malachite of Chessy.

R. Schindler reported **dihydrated zinc heptoxycarbonate**, $\text{ZnCO}_3 \cdot 7\text{ZnO} \cdot 2\text{H}_2\text{O}$, and **dihydrated zinc trioxycarbonate**, $\text{ZnCO}_3 \cdot 3\text{ZnO} \cdot 2\text{H}_2\text{O}$, to be formed when the corresponding basic zinc sulphate is boiled with a soln. of sodium carbonate. P. A. von Bonsdorff made the tetrahydrate by the action of a stream of carbon dioxide on water with zinc oxide in suspension. E. Dittler states that it is doubtful if there is such a compound as **dihydrated zinc dioxycarbonate**, $\text{ZnCO}_3 \cdot 2\text{ZnO} \cdot 2\text{H}_2\text{O}$, or $\text{Zn}_3(\text{OH})_4\text{CO}_3$. According to D. Strömholm, soln. with different proportions of carbon dioxide are in equilibrium with hydrated **zinc trioxydicarbonate**, $2\text{ZnCO}_3 \cdot 3\text{ZnO} \cdot n\text{H}_2\text{O}$. The *monohydrate* was reported by P. A. von Bonsdorff as a result of exposing zinc covered with water to the air. R. Schindler precipitated a soln. of a zinc salt with sodium carbonate, and he found that the product dried at 100° had the composition of a trihydrate: $2\text{ZnCO}_3 \cdot 3\text{ZnO} \cdot 3\text{H}_2\text{O}$, which A. Werner formulated

According to K. Kraut, the *tetrahydrate* is obtained by pouring a soln. of a zinc salt into a sat. soln. of alkali carbonate; by boiling zinc dust with an excess of carbonic acid; and, according to H. Mikusch, by the hydrolysis of zinc carbonate by boiling water. By the prolonged action of alkali carbonate, the basic salt is finally converted into zinc oxide. H. Rose, and J. B. J. D. Boussingault prepared what he regarded as **monohydrated zinc monoxycarbonate**, $\text{ZnCO}_3 \cdot \text{ZnO} \cdot \text{H}_2\text{O}$, and K. Feist prepared the same salt by using the soln. warmed to 30° , and drying the product at 100° ; the trihydrate is said to be formed by using cold soln. and drying the precipitate in air. C. Perrier represents the composition of the mineral *rosasite* as a basic zinc copper carbonate, $(\text{Zn}, \text{Cu})\text{CO}_3 \cdot \text{Cu}(\text{OH})_2$, resembling malachite, with part of the zinc replaced by copper. K. Kraut made **hydrated zinc dioxytricarboante**, $3\text{ZnCO}_3 \cdot 2\text{ZnO} \cdot n\text{H}_2\text{O}$, by working with dil. soln. at 2° . J. Smithson's, and A. Cossa's analyses of hydrozincite correspond closely with this product; and H. Rose also obtained a similar product by working with very dil. soln. H. Rose reported **monohydrated zinc monoxydicarbonate**, $2\text{ZnCO}_3 \cdot \text{ZnO} \cdot \text{H}_2\text{O}$, to be formed by the action of a soln. of sodium hydrocarbonate on zinc carbonate; J. Lefort found the product to be trihydrated. C. E. Jansen, J. E. Herberger, and C. Frederking reported **trihydrated zinc trioxydicarbonate**, $2\text{ZnCO}_3 \cdot 3\text{ZnO} \cdot 3\text{H}_2\text{O}$, to be formed by the action of sodium carbonate on a soln. of zinc salt; and P. A. Favre, **hexahydrated zinc pentoxytricarboante**, $3\text{ZnCO}_3 \cdot 5\text{ZnO} \cdot 6\text{H}_2\text{O}$, by the action of cold water on zinc ammino-carbonate. R. Hinsberg prepared a basic zinc carbonate by the joint action of carbon dioxide and ammonia at 80° on a conc. soln. of zinc sulphate or chloride. F. Wöhler found the basic salt is deposited in small shining crystals when an aq. soln. of potassium or sodium zincate is exposed to air.

R. Schindler stated that 0.3-0.5 part of basic zinc carbonate dissolves in a litre of water and the salt separates from the soln. when heated, without redissolving on cooling. R. Fresenius said 0.0224 part of the basic salt dissolves in a litre of water. A. Naumann said the basic salt is insoluble in acetone. R. H. Brett, and G. C. Wittstein found the basic salt dissolves readily in a cold aq. soln. of ammonium nitrate or chloride, and the soln., according to L. Thompson, gives off ammonia when heated. A. Terreil said basic zinc carbonate dissolves in a soln. of all the ammonium salts, excepting the sulphide. C. Zenghelis found that bright silver foil is dissolved when exposed for 15 days, about 5 cms. away from basic zinc carbonate. M. Kohn found basic zinc carbonate, formed in cold soln., completely precipitates ferric salts, and aluminium or uranium nitrate in cold soln., and chromic salts partly in the cold, and completely when heated.

As previously indicated, H. Rose obtained evidence of the formation of **basic cadmium carbonates**, but the subject was not investigated further. K. Kraut was unable to prepare a basic carbonate of cadmium. Only a very small quantity of cadmium carbonate is dissolved by aq. carbonic acid, even under a press. of several atm. The precipitate obtained by adding cadmium sulphate to a soln. of sodium carbonate consists of cadmium carbonate, CdCO_3 , mixed with a small quantity of cadmium oxy-sulphate, $2\text{CdO}.\text{SO}_3$; whilst by adding cadmium nitrate to an excess of ammonium carbonate, the carbonate $\text{CdCO}_3.\frac{1}{2}\text{H}_2\text{O}$ is obtained. O. Schneider found native basic cadmium carbonate in the oxidation-zone of the copper deposits of Otavi (S.W. Africa). He named it *otavite*. It forms white to red, crystalline crusts on the lining cavities; it has a strong lustre, inclined to metallic-adamantine in character. The minute, curved rhombohedra have an angle of about 80° . Analysis shows the mineral to be a basic cadmium carbonate containing 61.5 per cent. of cadmium.

C. Arnold¹⁰ found that ammoniacal soln. of ammonium carbonate gave a precipitate with zinc salt soln., which is soluble in an excess. H. Brandhorst found native calamine dissolves in aq. ammonia only in the presence of ammonium salts. V. Lindt found that raw calamine gives up all its zinc to an ammoniacal soln. of ammonium carbonate, but calcined calamine may not do so if a *zinc ferrite*, $\text{Zn}(\text{FeO}_2)_2$, is formed. F. de Lassone, and C. Roloff found that zinc filings and zinc oxide readily dissolve in a soln. of ammonium carbonate, with brisk effervescence in the former case. The evaporation of the soln. furnishes white crystals. The sat. soln. gives a white precipitate when treated with acids; and it becomes turbid when treated with an excess of water—because, said G. Bonnet, a compound richer in zinc oxide is precipitated. G. Bonnet also prepared a crystalline powder by digesting zinc oxide with an aq. soln. of ammonium carbonate. According to F. Wöhler, when zinc chloride is dropped into an excess of aq. ammonia, and the product mixed with ammonium carbonate, there are formed, on exposure to air, stellate masses of acicular crystals which are insoluble in water, and have a strong ammoniacal odour; they become turbid when exposed to air, and lose ammonia until a white powder is produced, which when heated evolves water and ammonia, leaving 62.2 per cent. of zinc oxide as residue. P. A. Favre reported that if freshly precipitated zinc carbonate be washed with an aq. soln. of ammonium carbonate, the filtrate deposits rectangular prisms or stellate masses of needles. The composition corresponds with **zinc monammino-carbonate**, $\text{ZnCO}_3.\text{NH}_3$. With cold water, pseudomorphs of the oxycarbonate $3\text{ZnCO}_3.5\text{ZnO}.6\text{H}_2\text{O}$ are formed. The ammino-salt does not change when exposed to air, or when treated with alcohol; and when slowly heated, it gives a sublimate of ammonium carbonate. G. Kassner electrolyzed a soln. of ammonium carbonate with a zinc rod as positive pole, and obtained white crystals of **zinc ammonium hydroxydicarbonate**, $2\text{ZnCO}_3.\text{Zn}(\text{OH})_2$. NH_4OH , which remain unchanged at 150° . G. Thomas also made some observations on this subject. For the action of ammonium carbonates on cadmium compounds, *vide supra*, cadmium oxide.

Our knowledge of the complex zinc carbonates is imperfect and fragmentary.

R. Schindler¹¹ reported that the gelatinous precipitate produced by adding an excess of potassium carbonate to a zinc salt soln. at ordinary temp. is a mixture of basic zinc carbonate and a **potassium zinc carbonate**. H. St. C. Deville obtained six-sided prisms of what he regarded as an acid double carbonate, $4K_2O \cdot 6ZnO \cdot 11CO_2 \cdot 8H_2O$, by mixing a boiling soln. of zinc chloride with a boiling sat. soln. of potassium carbonate or hydrocarbonate, and allowing the mixture to stand for some time; the product was washed with cold water and dried in vacuo. H. St. C. Deville also prepared a **sodium zinc carbonate**, $3Na_2O \cdot 8ZnO \cdot 11CO_2 \cdot 8H_2O$, which K. Kraut considers should be $Na_2O \cdot 3ZnO \cdot 4CO_2 \cdot 3H_2O$. It is also considered possible that F. Wöhler's product obtained by exposing a soln. of sodium zincate to the atm. is a sodium zinc carbonate. W. Smith was unable to prepare the compound, $NaO \cdot Zn(NaCO_3)$, reported by F. Wöhler to be produced when a soln. of sodium carbonate acts on zinc with the escape of hydrogen, for, with a hot soln., a white deposit consisting mainly of zinc oxide is formed, and the filtrate contains no zinc. It is, however, possible that with a cold soln. a compound is slowly produced which is decomposed by heat. H. W. F. Wackenroder, as previously indicated, found that zinc oxide is not attacked by a boiling soln. of sodium carbonate. The so-called *aurichalcite* is regarded as a native form of *zinc cupric carbonate*, or as a mixture of the basic carbonates of these elements. This is confirmed by the analyses of S. L. Penfield, T. Böttger, A. Connell, A. Delesse, A. Belar, J. H. Collins, E. Jannetaz, and L. Michel. C. Perrier's analysis of *rosasite* corresponds with a kind of *zinc-malachite*, $(Cu, Zn)CO_3 \cdot (Cu, Zn)(OH)_2$. F. K. Biehl studied the aurichalcites of Tsumeb; those with a composition $3(Cu, Zn)CO_3 \cdot 4(Cu, Zn)(OH)_2$ with $Cu : Zn = 2 : 1$ and sp. gr. 4.201, and $4(Cu, Zn)CO_3 \cdot 5(Cu, Zn)(OH)_2$ with $Cu : Zn = 3 : 2$ and sp. gr. 4.137, are called *paraaurichalcites*; while material with $(Cu, Zn)CO_3 \cdot (Cu, Zn)(OH)_2$ with $Cu : Zn = 9 : 2$ and sp. gr. 4.104 is called *cuprozincite*. E. W. Provost found a deposit on the brass binding screws of a Leclanché cell which had the composition of a *zinc copper aminochloride*, $Cu_2Zn_4Cl_6(NH_3)_4CO_3$, but there is nothing to show that this product is a chemical individual.

§ 19. Zinc and Cadmium Nitrates

A soln. of **zinc nitrate** is obtained by dissolving the metal, the oxide, or hydroxide in nitric acid; and when the conc. soln. is allowed to crystallize, **hexahydrated zinc nitrate**, $\text{Zn}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$, is obtained in "colourless, flattened, striated, four-sided prisms, with four-sided summits." This formula agrees with the analyses of T. Graham,¹ and N. A. E. Millon, but R. Schindler thought that $7\text{H}_2\text{O}$ best represented his analysis. Hydrates with $1\frac{1}{2}$, 2, 3, 4, $5\frac{1}{2}$, 6, and $9\text{H}_2\text{O}$ have not been reported, but the reports of several of these are based on insufficient evidence. The equilibrium conditions of the ennea-, hexa-, and tri-hydrates are illustrated in Fig. 50, which is based on the solubility determinations of F. Mylius and R. Funk between -29° and 36.4° ; and of J. Ordway at higher temp. The percentage solubilities, S, are:

S . . .	-29°	-20°	-17°	0°	18°	36.4°	35°	40°	45.5°
	39.40	42.00	44.80	48.66	53.89	63.68	65.52	67.42	77.80%
Solid phase . . .	$\text{Zn}(\text{NO}_3)_2 \cdot 9\text{H}_2\text{O}$			$\text{Zn}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$			$\text{Zn}(\text{NO}_3)_2 \cdot 3\text{H}_2\text{O}$		

For the ice-line, R. Funk gave 35.03 per cent. at -16° , and F. Rüdorff, 18.43 per cent. at -7.4° and 11.19 per cent. at -3.6° . P. Dutoit and E. Grobet measured

FIG. 50.—Solubility Curves of Zinc Nitrate.

the temp. changes attending the progressive addition of sodium hydroxide to soln. of zinc nitrate and observed breaks corresponding with the formation of **zinc hydroxynitrate**, $\text{Zn}(\text{OH})\text{NO}_3$, **zinc hydroxide**, and **sodium zincate**.

A. Ditte made **hemitrihydrated zinc nitrate**, $\text{Zn}(\text{NO}_3)_2 \cdot 1\frac{1}{2}\text{H}_2\text{O}$, by heating the hexahydrate until red vapours appear and dissolving the cold mass in monohydrated sulphuric acid. Much heat is thereby developed, and when the soln. cools, transparent, lustrous crystals appear. A. M. Wasilieff prepared what he regarded as **dihydrated zinc nitrate**, $\text{Zn}(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O}$, by cooling a soln. of zinc oxide in 97 per cent. nitric acid. H. C. Jones and H. P. Bassett found that **tri-hydrated zinc nitrate**, $\text{Zn}(\text{NO}_3)_2 \cdot 3\text{H}_2\text{O}$, separates from

the aq. soln. at 36° in needle-like crystals. R. Funk obtained the trihydrate by driving off two-thirds of the water from the hexahydrate, melting the product at 37° with more hexahydrate, rapidly cooling to 30° , and again heating to 34° . He also made it by keeping the hexahydrate at 37° – 40° for many days, and by heating the hexahydrate with a little nitric acid on a water-bath and evaporating the soln. over sulphuric acid. The trihydrate is the stable solid phase in the presence of aq. soln. above 36° . A. M. Wasilieff claimed to have made rhomboidal crystals of **tetrahydrated zinc nitrate**, $\text{Zn}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$, from a soln. of zinc oxide in nitric acid of sp. gr. 1.4. According to A. M. Wasilieff, the so-called **hemihenadeca-hydrated zinc nitrate**, $\text{Zn}(\text{NO}_3)_2 \cdot 5\frac{1}{2}\text{H}_2\text{O}$, is a eutectic of

the hexa- and tetra-hydrates which freezes at 35.4° . H. C. Jones and H. P. Bassett made **enneahydrated zinc nitrate**, $\text{Zn}(\text{NO}_3)_2 \cdot 9\text{H}_2\text{O}$, by cooling an aq. soln. of zinc nitrate to about -18° , R. Funk said -20° .

The crystallization of a conc. soln. of cadmium, or of cadmium oxide or hydroxide in nitric acid, furnishes crystals of **tetrahydrated cadmium nitrate**, $\text{Cd}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$, "in prisms and needles, united," said F. Stromeyer, "in radiating masses." B. Franz studied the preparation of cadmium nitrate. The crystals are dissolved in hot water, and the soln. again crystallized. The preparation of highly purified cadmium nitrate has been discussed by W. S. Lorimer and E. F. Smith, and by E. A. Partridge. A. M. Wasilieff made the anhydrous salt by evaporating the water from the hydrate. Hydrates have been reported containing 2, 4, and 9 mols of water of crystallization. The range of stability of the two latter in aq. soln. is illustrated by the curve, Fig. 51. The percentage solubilities, S , are:

S	-8.6° 25.5	-14.5° 35.9	-16° 36.3	-13° 37.3	0° 52.3	1° 52.6	30° 58.4	40° 61.4	59.5° 56.6
Solid phase	Ice		$\text{Cd}(\text{NO}_3)_2 \cdot 9\text{H}_2\text{O}$			$\text{Cd}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$			

The determinations from -4.2° to -8.6° are by F. Rüdorff, and the value at 59.5° is by J. Ordway; the remainder are by R. Funk. A. M. Wasilieff traced the solubility curve of the anhydrous salt, and of the solid tetrahydrate, and found a break beyond the m.p. of the hydrate, 59.5° , descending to 44.5° , which is the eutectic temp. of the mixture, and corresponds with $\text{Cd}(\text{NO}_3)_2 + 2.65\text{H}_2\text{O}$; the curve then rises continuously to the m.p. of the anhydrous salt.

H. Lescœur prepared needle-like crystals of **dihydrated cadmium nitrate**, $\text{Cd}(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O}$, by adding conc. nitric acid to a soln. of the tetrahydrate. R. Funk also obtained it by keeping the tetrahydrate in a molten condition for some days, but found it difficult to isolate the crystals from the viscid mass. H. C. Jones and H. P. Bassett crystallized **enneahydrated cadmium nitrate**, $\text{Cd}(\text{NO}_3)_2 \cdot 9\text{H}_2\text{O}$, from a supersaturated soln. of cadmium nitrate cooled to

-16° . According to R. Funk, the crystals of the tetrahydrate in the soln. below 0° slowly pass into the higher hydrate. If the supersaturated soln. be cooled to -30° , crystals of the enneahydrate appear, the temp. rises to -16° and the cryohydrate is formed. A. M. Wasilieff could obtain neither the di- nor hexahydrates reported by R. Funk; and he represented the low temp. crystals as the octohydrated salt. M. Hasselblatt measured the velocities of crystallization at 1 and 1000 kgms. per sq. cm. press. and found a slight increase with rise of press.

F. W. Clarke² gave 2.065 for the **specific gravity** of hexahydrated zinc nitrate at 14° , and 2.455 for the sp. gr. of tetrahydrated cadmium nitrate at 17° . The sp. gr. of aq. soln. of zinc nitrate have been measured by A. C. Oudemans, D. Dijken, J. Wagner, H. T. Barnes and A. P. Scott, H. C. Jones and F. H. Getman, F. Mylius and R. Funk, R. Dietz, etc. B. Franz found at 17.5° , for soln. with varying percentages of cadmium nitrate:

Sp. gr.	1	5	10	15	25	30	35	45	50
	1.0099	1.0496	1.0968	1.1476	1.2640	1.3268	1.3906	1.5258	1.5984

G. Happart measured the contraction which occurs when zinc nitrate is dissolved in water. The sp. gr. of aq. soln. of cadmium nitrate has been measured by C. A. Valson, O. Grotrian, J. Wagner, F. J. Wershoven, R. de Muyneck, M. le Blanc and P. Rohland, H. C. Jones and F. H. Getman, etc. B. Franz found at 15° for soln. with varying percentages of cadmium nitrate:

FIG. 51.—Solubility Curves of Cadmium Nitrate.

	5	10	15	20	25	35	45	5
Sp. gr. .	1.0528	1.0978	1.1516	1.2134	1.2842	1.4372	1.6471	1.7608

H. Sentis³ found the **surface tension** of soln. of zinc nitrate containing n mols of salt in 100— n mols of water to be $2.5n$. C. A. Valson observed the heights to which soln. of cadmium nitrate rise in capillary tubes. J. Wagner found the **viscosity** of aq. soln. of zinc and cadmium nitrates to be at 25° (water unity) :

	N .	$\frac{1}{2}N$.	$\frac{1}{3}N$.	$\frac{1}{4}N$.
Zn(NO ₃) ₂ .	1.1642	1.0857	1.0390	1.0186
Cd(NO ₃) ₂ .	1.1648	1.0742	1.0380	1.0117

J. C. Graham found the **diffusion coeff.** of 3 to 5 per cent. soln. of zinc nitrate to be $k=0.640$. J. Thovert also measured this constant.

The **melting point** of anhydrous cadmium nitrate was found by A. M. Wasilieff⁴ to be 350° ; that of the tetrahydrated cadmium nitrate, 59.5° ; and that of hexahydrated zinc nitrate was found by J. Ordway to be 36.4° . M. Hasselblatt found the m.p. of tetrahydrated cadmium nitrate was raised 7° when the press. was increased from 1 to 1000 kgrms. per sq. cm. W. A. Tilden gave 36.4° and J. L. R. Morgan and F. T. Owen, 44.07° ; J. Ordway gave 131° for the **boiling point** of the hexahydrate. A. Vogel and C. Reischauer found that the hexahydrate loses two-thirds of its water in vacuo over sulphuric acid; T. Graham said half the water is lost. A. Vogel and C. Reischauer added that nitric acid is lost when the nitrate is warmed at 100° for a long time, and J. I. Pierre, that all the water is gradually lost when the nitrate is heated for a long time in a stream of air at 105° , while R. Schindler found that when the nitrate is heated above 100° , it loses nitric acid, nitrogen peroxide, and oxygen. A. Ditte said that the hemitrihydrate melts when heated, and gives off water and nitrous vapours. R. Funk found that trihydrated zinc nitrate melts at 45.5° , and on exposure to air, it is very soon converted into the hexahydrate. A. M. Wasilieff found the eutectic temp. of the tetra- and di-hydrates is 38.4° , and of the hexa- and tetra-hydrates, 35.4° ; he added that the m.p. of the tetrahydrate is 45.5° . N. A. Puschin found that the transition point of $\text{Cd}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O} \rightarrow \text{Cd}(\text{NO}_3)_2$ occurs at 58.7° under atm. press., and at a press. p kgrms. per sq. cm., the transition temp., θ , is $\theta = 58.7 + 0.00813p$.

According to K. von Hauer, and A. Hébert and G. Reynaud, tetrahydrated cadmium nitrate melts in its water of crystallization at 100° , at 59.5° , according to J. Ordway, R. Funk, and W. A. Tilden. J. Ordway gave 132° for the b.p. A. Hébert and G. Reynaud found the tetrahydrate, in vacuo, loses water and nitrous vapours, and the residue, according to H. Lescœur, contains insoluble cadmium oxide, and the soluble dihydrate. A. Ditte found a slight smell of nitrous fumes is given off by the molten salt. According to N. A. Puschin, the m.p. is 91° at 8000 kgrms. press., and when the press. exceeds 8000 kgrms., the m.p. is depressed. R. Funk gave 130° for the m.p. of dihydrated cadmium nitrate. J. L. R. Morgan and F. T. Owen found the **latent heat of fusion** of trihydrated zinc nitrate to be 34.3 cal. per grm., and N. A. Puschin obtained 26.3 Cals. per mol at atm. press. for tetrahydrated cadmium nitrate.

F. Rüdorff⁵ measured the **lowering of the freezing point** of soln. of zinc and cadmium nitrates; and H. C. Jones and F. H. Getman found for soln. containing M mols of zinc nitrate per litre :

M .	0.065	0.129	0.258	0.516	1.290	1.548	1.806	2.064	2.580
$\delta\theta$.	0.322°	0.633°	1.281°	2.812°	8.930°	11.800°	14.720°	18.240°	27.000°
$\delta\theta/M$.	4.95	4.90	4.96	5.45	6.92	7.69	8.15	8.83	10.46

and similarly for soln. of cadmium nitrate :

M .	0.0845	0.1691	0.3382	0.6764	1.0146	1.6910	2.7056
$\delta\theta$.	0.443	0.865	1.802	2.028	6.540	12.930	26.000
$\delta\theta/M$.	5.24	5.12	5.33	5.96	6.45	7.65	9.61

J. L. R. Morgan and F. T. Owen studied hydrated zinc nitrate as a solvent for the

f.p. method of determining mol. wt. and obtained 58.6 for the f.p. constant. J. Schröder and H. Steiner found the **molecular weight** of zinc nitrate in methyl acetate as solvent, to be 100.7 to 189.1—calculated for $\text{Zn}(\text{NO}_3)_2$, 189.5. G. Tammann measured the **osmotic pressure** of soln. of zinc nitrate. G. Tammann measured the **lowering of the vapour pressure** of water at 100° , and found that with 9.31, 32.53, and 78.06 grms. of zinc nitrate per 100 grms. of water, the vap. press. was lowered 16.3 mm., 78.0 mm., and 231.5 mm. respectively; and with 8.18, 60.37, and 86.73 grms. of cadmium nitrate in 100 grms. of water, the vap. press. was lowered 10.7 mm., 102.2 mm., and 159.5 mm. respectively. H. Lescœur found the vap. press. of a sat. soln. of zinc nitrate at 20° to be 9.6 mm.; he also found the vap. press. of the trihydrate to be less than 2 mm. at 20° , and for the hexahydrate, 10 mm. at 20° . H. Lescœur gave 10 mm. for the dissociation press. of sat. soln. of cadmium nitrate at 20° , for $\text{Cd}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$, 9.3 mm.; for $\text{Cd}(\text{NO}_3)_2 \cdot 2\frac{1}{2}\text{H}_2\text{O}$, 8.4 mm.; and for $\text{Cd}(\text{NO}_3)_2 \cdot 2\frac{1}{2}\text{H}_2\text{O}$, below 3 mm.

J. C. G. de Marignac⁶ found the **specific heat** of soln. of zinc nitrate with $10\text{H}_2\text{O}$, $25\text{H}_2\text{O}$, $50\text{H}_2\text{O}$, and $200\text{H}_2\text{O}$ to be respectively 0.5906, 0.7176, 0.8234, and 0.9461 between 20° and 52° . M. Berthelot gave for the **heat of formation**, $(\text{Zn}, \text{N}_2, 3\text{O}_2, \text{Aq.}) = \text{Zn}(\text{NO}_3)_2\text{aq.} + 131.7$ Cals.; and J. Thomsen gave $(\text{Zn}, \text{O}_2, \text{N}_2\text{O}_4, 6\text{H}_2\text{O}) = 140.82$ Cals.; $(\text{Cd}, \text{N}_2, 3\text{O}_2, \text{H}_2\text{O}) = 113.3$ Cals.; and $(\text{Cd}, \text{N}_2, 3\text{O}_2, 4\text{H}_2\text{O}) = 121.16$ Cals. For the **heat of dilution**, J. Thomsen gave for $\text{Zn}(\text{NO}_3)_2 + 10\text{H}_2\text{O}$ when diluted with

Mols H_2O	.	.	15	20	50	100	200
Cals.	.	.	0.914	1.148	1.203	1.111	1.071 Cals.

for a mol of $\text{Zn}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$ with 400 mols of water, -5.84 Cals., for a mol of $\text{Cd}(\text{NO}_3)_2 \cdot \text{H}_2\text{O}$, 4.18 Cals., and for a mol of $\text{Cd}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$, -5.04 Cals. For the **heat of neutralization** in very dil. soln., J. Thomsen gave for $\text{Zn}(\text{OH})_2 + 2\text{HNO}_3 = 2\text{H}_2\text{O} + \text{Zn}(\text{NO}_3)_2 + 9.915$ Cals., and M. Berthelot gave 9.8 Cals.; J. Thomsen also gave for $\text{Cd}(\text{OH})_2 + 2\text{HNO}_3 = 2\text{H}_2\text{O} + \text{Cd}(\text{NO}_3)_2 + 20.243$ Cals. F. Braun found that but 77 per cent. of the heat of formation of cadmium nitrate can be converted into electrical energy.

H. C. Jones and F. H. Getman⁷ measured the **index of refraction**, μ , for soln. containing M mol of zinc nitrate per litre:

M	.	.	0.065	0.129	0.258	0.516	1.132	1.548	2.064	2.580
μ	.	.	1.32766	1.32949	1.33272	1.34021	1.35374	1.36775	1.37981	1.39098

and for cadmium nitrate:

M	.	.	0.0845	0.1691	0.6746	1.0146	1.6910	2.3674	3.0438	3.3820
μ	.	.	1.32355	1.33070	1.34588	1.35580	1.36794	1.37379	1.40792	1.41534

Measurements of soln. of zinc nitrate were also made by D. Dijken, and of cadmium nitrate by M. le Blanc and P. Rohland, and by R. de Muynck. A. Hébert and G. Reynaud studied the specific absorption of **X-rays** by cadmium nitrate. A. E. Garrett found that above 360° , cadmium nitrate can ionize the surrounding air. W. N. Hartley has measured the absorption spectrum of soln. of zinc nitrate. J. R. Collins measured the **ultra-red absorption spectrum** of aq. soln. of the nitrate.

The **electrical conductivity** of soln. of zinc nitrate has been determined by S. Arrhenius,⁸ H. C. Jones and co-workers, and C. Freund. H. C. Jones gave for soln. containing a mol of zinc nitrate in v litres the mol. conductivities μ :

v	.	.	4	8	52	128	512	1024	2048	4096
μ at 0°	.	.	80.6	87.6	100.0	110.4	114.1	117.1	120.4	124.4
μ at 65°	.	.	258.65	289.67	343.09	384.97	415.20	428.50	434.82	445.53

The temp. coeff. of the conductivity has been measured by H. C. Jones and co-workers. A. E. Garrett found that the conductivity of zinc nitrate is increased by raising the temp. O. Grotrian, E. Bouty, S. Labendzinsky, and F. J. Wershoven,

measured the electrical conductivity of soln. of cadmium nitrate. H. C. Jones and F. H. Getman found at 0° :

ν	.	.	0.29	0.42	0.59	0.98	1.48	2.95	5.91	11.83
μ	.	.	10.60	27.30	38.43	57.10	64.6	81.0	92.6	99.7
α	.	.	5.30	13.6	19.2	28.6	32.3	40.5	46.3	49.9

where α denotes the values for the percentage **degree of ionization** ; for soln. of zinc nitrate the percentage degree of ionization is :

ν	.	.	.	4	8	32	128	512	1024	2048	4096
α at 0°	.	.	.	64.8	70.4	80.4	88.7	91.9	94.1	96.2	100.0
α at 65°	.	.	.	58.1	65.0	77.0	86.4	93.2	96.2	97.6	100.0

R. Benz studied the conductivity of alcoholic soln. of cadmium nitrate. S. Labendzinsky also measured the degree of ionization of soln. of zinc and cadmium nitrates. The *temperature* coeff. of the conductivity has been measured by O. Grottrian, and F. J. Wershoven. B. Piesch measured the effect of *pressure* on the conductivity of soln. of zinc nitrate. C. L. Weber, and A. Chassy measured the **transport numbers** of the ions with soln. of zinc nitrate ; and G. Carrara with aq. and alcoholic soln. of cadmium nitrate. S. Labendzinsky measured the **potential** of zinc against $N\text{-Zn}(\text{NO}_3)_2$ and a calomel electrode. E. Bouty, and A. Ebeling measured the **thermoelectric force** of zinc against soln. of zinc nitrate ; and E. Bouty, and A. Hagenbach, of cadmium against soln. of cadmium nitrate.

Basic salts.—According to J. Walker and E. Aston,⁹ the **hydrolysis** of a $\frac{1}{2}N$ -soln. of zinc nitrate at 80° is 0.019 per cent., and of a $\frac{1}{2}N$ -soln. of cadmium nitrate 0.014 per cent. A. Vogel and C. Reischauer found that a neutral soln. of zinc nitrate dissolves some zinc oxide ; and H. L. Wells obtained prismatic crystals of **trihydrated zinc monoxynitrate**, $\text{Zn}(\text{NO}_3)_2 \cdot \text{ZnO} \cdot 2\text{H}_2\text{O}$, in a similar manner. It furnishes different decomposition products when treated with alcohol or water. J. Ordway, and G. A. Bertels reported **trihydrated zinc monoxytrinitrate**, $3\text{Zn}(\text{NO}_3)_2 \cdot \text{ZnO} \cdot 3\text{H}_2\text{O}$; H. L. Wells, and G. A. Bertels reported **tetradecahydrated zinc trioxytetranitrate**, $4\text{Zn}(\text{NO}_3)_2 \cdot 3\text{ZnO} \cdot 14\text{H}_2\text{O}$, among the products of the decomposition of the zinc monoxynitrate by water. A. Ditte prepared **hydrated zinc dioxynitrate**, $\text{Zn}(\text{NO}_3)_2 \cdot 2\text{ZnO} \cdot n\text{H}_2\text{O}$, by washing the yellow powder— $8\text{ZnO} \cdot \text{N}_2\text{O}_5 \cdot 4\text{H}_2\text{O}$ —with water, until the runnings were free from zinc nitrate. The product decomposes when heated without melting ; it is soluble in nitric acid ; and it is not acted on by a soln. of zinc nitrate. G. A. Bertels and J. Ordway boiled the neutral zinc nitrate until it had lost 42 per cent. in weight, and found that the solidified glassy residue had the composition : $\text{Zn}(\text{NO}_3)_2 \cdot 3\text{ZnO} \cdot 3\text{H}_2\text{O}$ —**trihydrated zinc trioxynitrate**. C. F. Gerhardt prepared this salt in prismatic needles. By heating a soln. of two parts of zinc nitrate with one part of water in a sealed tube at 310° M. Athanasesco prepared white needles of the same composition : $\text{Zn}(\text{NO}_3)_2 \cdot 3\text{ZnO} \cdot 3\text{H}_2\text{O}$, or, as he puts it, $\text{HO} \cdot \text{NO} : (\text{OZnOH})_2$. The crystals lose their water at 180° ; they are insoluble in water and soluble in dil. acids. M. Athanasesco also prepared the *tetrahydrate* in white needles by boiling a very conc. neutral soln. of zinc nitrate (1 : 1) with zinc. They lose their water of crystallization at 130°, and decompose when heated above 180°. R. Schindler also prepared a white powder which he regarded as a *dihydrate* by digesting the yellow powder, $8\text{ZnO} \cdot \text{N}_2\text{O}_5 \cdot 4\text{H}_2\text{O}$, with a neutral soln. of zinc nitrate.

A. Terreil prepared what he regarded as **pentahydrated zinc tetroxynitrate**, $\text{Zn}(\text{NO}_3)_2 \cdot 4\text{ZnO} \cdot 5\text{H}_2\text{O}$, by the action of an excess of zinc on a boiling soln. of zinc nitrate, and cooling the syrupy mass obtained by evaporation. The undecomposed nitrate was removed by washing with water. The fine acicular crystals are insoluble in cold water, and decompose when heated. G. Rousseau and G. Tite obtained the *hexahydrate* by heating in a sealed tube at 100°, the hydrated normal salt mixed with marble. The needle-like crystals are slowly decomposed by cold, and rapidly by boiling water. J. Habermann obtained what he regards as a *hemihenadeca hydrate*, $\text{Zn}(\text{NO}_3)_2 \cdot 4\text{ZnO} \cdot 5\frac{1}{2}\text{H}_2\text{O}$, by the action of dil. ammonia on a neutral soln. of

zinc nitrate. The crystals were insoluble in cold water. M. Berthelot has also studied this basic salt. A. Vogel and C. Reischauer prepared fine crystals of what they regarded as **zinc heptoxydinitrate**, $9\text{ZnO} \cdot 2\text{N}_2\text{O}_5$, or $2\text{Zn}(\text{NO}_3)_2 \cdot 7\text{ZnO}$, by warming the neutral salt for a long time at 100° . J. Ordway and G. A. Bertels prepared **trihydrated zinc pentoxynitrate**, $\text{Zn}(\text{NO}_3)_2 \cdot 5\text{ZnO} \cdot 3\text{H}_2\text{O}$, by the action of water on trihydrated zinc monoxynitrate. J. Ribau also obtained what he regarded as a *heptahydrate* and an *octohydrate* by the action of an excess of zinc on a boiling soln. of zinc nitrate. According to P. Grouvelle, **tetrahydrated zinc heptoxynitrate**, $8\text{ZnO} \cdot \text{N}_2\text{O}_5 \cdot 4\text{H}_2\text{O}$, or $\text{Zn}(\text{NO}_3)_2 \cdot 7\text{ZnO} \cdot 4\text{H}_2\text{O}$, is produced by adding insufficient ammonia required for the complete precipitation of zinc nitrate. According to R. Schindler, the precipitate retains some ammonia. When the normal salt is heated until it has become nearly solid, P. Grouvelle found the product corresponded with the *dihydrate* of zinc heptoxynitrate. R. Schindler also said that if the molten nitrate be heated until it becomes opaque, and then washed with water, the yellow powder which remains has the same composition.

H. C. Klinger obtained iridescent rhombic plates of **trihydrated cadmium monoxynitrate**, $\text{Cd}(\text{NO}_3)_2 \cdot \text{CdO} \cdot 3\text{H}_2\text{O}$, by adding lead hydroxide to a hot soln. of cadmium nitrate; by heating cadmium nitrate; and by dissolving cadmium hydroxide in a soln. of the nitrate. The product was washed with alcohol and dried in a desiccator. H. L. Wells obtained prismatic crystals from a sat. soln. of cadmium oxide in a conc. soln. of the nitrate. The product loses a mol of water between 120° and 130° ; it is decomposed by water and alcohol. The latter acts more rapidly than water, and the final product is the hydroxide. A. Ditte also obtained this compound. According to H. L. Wells, H. C. Klinger's analyses agree with $4\text{Cd}(\text{NO}_3)_2 \cdot 3\text{CdO} \cdot 7\text{H}_2\text{O}$. G. Rousseau and G. Tite reported the formation of lamellar crystals of **octohydrated cadmium trioxynitrate**, $2\text{Cd}(\text{NO}_3)_2 \cdot 3\text{CdO} \cdot 8\text{H}_2\text{O}$, by heating the normal nitrate with marble in a sealed tube, between 300° and 350° , and washing with boiling alcohol. The product is immediately decomposed by water to amorphous cadmium henadecaoxynitrate, $\text{Cd}(\text{NO}_3)_2 \cdot 11\text{CdO} \cdot 11\text{H}_2\text{O}$, by adding very dil. aq. ammonia to a boiling conc. soln. of normal cadmium nitrate. The product is but sparingly soluble in water.

Zinc nitrate deliquesces in air; K. von Hauer, and W. Meissner¹⁰ noted that tetrahydrated cadmium nitrate deliquesces in air. Both zinc and cadmium nitrates are readily soluble in **water**. J. G. Children noted that tetrahydrated cadmium nitrate is soluble in **ethyl alcohol** but does not impart any peculiar colour to the flame. G. Carrara and L. d'Agostini found that cadmium nitrate is soluble in **methyl alcohol**; P. Dutoit, and R. Benz, in **acetone**; A. Naumann in **ethyl acetate**; and L. Kahlenberg, in **pyridine**. H. Demarçay found that **lead hydroxide** precipitates the zinc as basic nitrate completely from a soln. of the salt. A. Mailhe studied the action of **cupric hydroxide** on an aq. soln. of zinc nitrate and noted the formation of a basic salt, $\text{Zn}(\text{NO}_3)_2 \cdot 3\text{CuO} \cdot 3\text{H}_2\text{O}$. A. Mailhe found that with cadmium nitrate, **mercuric oxide** gives a white precipitate of the basic salt, $\text{CdO} \cdot \text{Hg}(\text{NO}_3)_2 \cdot 3\text{H}_2\text{O}$. M. C. de Schuyten found that **chlorine**, **bromine**, or **iodine** forms the zinc halide with aq. soln. of zinc nitrate. H. Demarçay found that zinc nitrate detonates when sprinkled on hot **carbon**, and gives a reddish flame. L. P. Perman found a reaction between **arsenious oxide** and cadmium nitrate. According to A. Ditte, hemitrihydrated zinc nitrate is readily soluble in **nitric acid**—100 parts of water at 13° dissolve 28 parts of the salt, and at 55° , 55 parts of the salt. K. Drücker found that when aq. **ammonia** is added to a soln. of zinc nitrate, an amorphous white precipitate of the basic salt is produced. E. C. Franklin and C. A. Kraus found that the soln. of zinc nitrate in aq. ammonia at once gives a precipitate with ammonium chloride, with ammonium bromide the precipitate is formed more slowly, and none with ammonium iodide; ammonium sulphide gives a white precipitate; ammonium chromate a flocculent precipitate; and ammonium borate, a white precipitate. F. M. G. Johnson and N. T. M. Wilsmore found cadmium nitrate is soluble in liquid ammonia. W. Herz studied the equilibrium

conditions in the reaction between **ammonium nitrate** and cadmium hydroxide: $\text{Cd}(\text{NO}_3)_2 + 2\text{NH}_4\text{OH} \rightleftharpoons \text{Cd}(\text{OH})_2 + 2\text{NH}_4\text{NO}_3$. A. Eckstädt studied the catalytic effect of cadmium nitrate on the reaction between nitric acid and iodine.

G. André prepared deliquescent crystals of **zinc tetrammino-nitrate**, $[\text{Zn}(\text{NO}_3)_2(\text{NH}_3)_4]_3 \cdot 2\text{H}_2\text{O}$, by passing ammonia through a soln. of zinc nitrate, and evaporating so as to avoid a rise of temp. F. Ephraim gave 206° for the decomposition temp. of zinc tetrammino-nitrate, and he found that the crystalline tetrammine changed into **zinc hexammino-nitrate**, $[\text{Zn}(\text{NH}_3)_6](\text{NO}_3)_2$, when treated with ammonia at 0° . The latter decomposed at 31.5° . M. I. Konowaloff measured the electrical conductivity of soln. of zinc tetrammino-nitrate, and likewise of soln. of **cadmium hexammino-nitrate**, $\text{Cd}(\text{NO}_3)_2 \cdot 6\text{NH}_3$. The anhydrous cadmium salt was prepared by G. André by saturating an ammoniacal soln. of cadmium nitrate with ammonia; the soln. gives a white precipitate when treated with cold water. Crystals of the monohydrate were also prepared by dissolving an excess of cadmium nitrate in 20 per cent. aq. ammonia. The voluminous precipitate dissolves when the mixture is alternately warmed and cooled. The salt blackens when heated and decomposes with a slight explosion. F. M. G. Johnson and N. T. M. Wilmore measured the e.m.f. of conc. cells of tetrahydrated cadmium nitrate in liquid ammonia at -33.5° . G. André prepared a **basic zinc tetrammino-nitrate**, $3\text{Zn}(\text{NO}_3)_2 \cdot 10\text{ZnO} \cdot 4\text{NH}_3 \cdot 18\text{H}_2\text{O}$, by the action of precipitated zinc oxide on a warm aq. soln. of ammonium nitrate. The salt is insoluble in cold water, and decomposed by warm water into zinc oxide, etc. H. Morin reported the formation of **ammonium cadmium nitrate**, by the action of a rod of cadmium on a soln. of ammonium nitrate.

M. Hasselblatt studied the fusion curves of isomorphous mixtures of tetrahydrated **cadmium and calcium nitrates**. The stable form of calcium nitrate furnishes a eutectic at 40.6° when 91 per cent. of $\text{Cd}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$ is present. The unstable form gives a continuous series of mixed crystals with the cadmium salt. The effect of increased press. up to 3000 kilos. per sq. cm. on the system has now been investigated. The general form of the diagram is unchanged. The press. temp. curve for mixed crystals containing a high proportion of the calcium salt could not be followed at higher press. on account of the rapid change of the calcium salt into the stable form. Excess of the cadmium salt inhibits this change, but as the press. increases, more cadmium salt is needed to produce this effect. With increasing press., the m.p. of the stable calcium salt rises much more rapidly than that of the unstable. The latter does not form mixed crystals with cadmium nitrate. The lowering of the m.p. of the stable calcium salt by the cadmium salt is independent of the press. With increasing press., the eutectic point moves towards the cadmium side; at 1000 kgrms. per sq. cm. it is at 79 per cent. calcium nitrate, 47.8° ; at 2000 krgms. per sq. cm. 74 per cent. and 55° ; and at 3000 kgrms. per sq. cm. 71 per cent. calcium nitrate and 61.5° .

§ 20. Zinc and Cadmium Phosphates

The mineral *hopeite* found in the calamine mines of Altenburg (Aix-la-Chapelle) was named by D. Brewster¹ after T. C. Hope of Edinburgh; A. Breithaupt called it prismatoidal *zincophyllite*. N. Nordenskiöld showed that it is probably a hydrated zinc phosphate with a little cadmium phosphate. A. des Cloizeaux, and C. Friedel and E. Sarasin showed that hopeite is essentially zinc orthophosphate, $\text{Zn}_3(\text{PO}_4)_2 \cdot 4\text{H}_2\text{O}$. A. Schrauf showed that hopeite is closely related to eggonite. L. J. Spencer showed that the mineral is dimorphous, and exists in rhombic and triclinic forms: the former is called hopeite, and the latter parahopeite; hopeite also occurs in two modifications— α -hopeite and β -hopeite—distinguished by their optical properties, and their dehydration curves. All three varieties are found at Brocken Hill (N.-W. Rhodesia).

E. Mitscherlich found that normal **zinc orthophosphate**, $\text{Zn}_3(\text{PO}_4)_2$, is precipitated on mixing a soln. of a zinc salt with ammonium, potassium, or sodium hydrophosphate, and he noted that the supernatant liquid becomes acidic. R. Schindler, and H. Debray found that when dil. soln. of zinc sulphate and sodium hydrophosphate are mixed in the cold, a translucent jelly is first produced, and this soon becomes opaque, and aggregates into a fine white crystalline powder; if the soln. are mixed boiling hot, no jelly is produced, but the pulverulent precipitate is produced at once. W. Heintz also obtained the same product by working with acetic acid soln. According to W. Heintz, and H. Debray, the same compound is also produced when zinc carbonate is digested with an aq. soln. of phosphoric acid, not in excess. A. de Schulten obtained artificial crystals of hopeite by mixing a soln. of 4.5 grms. of heptahydrated zinc sulphate in 2 litres of cold water with a soln. of dodecahydrated sodium hydrophosphate in a litre of cold water. According to A. de Schulten, the composition corresponds with $\text{Zn}_3(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$; C. Friedel and E. Sarasin gave $\text{Zn}_3(\text{PO}_4)_2 \cdot 4\text{H}_2\text{O}$; R. Schindler, and T. Graham, $\text{Zn}_{13}(\text{PO}_4)_2 \cdot 2\text{H}_2\text{O}$; W. Skey, $\text{Zn}_3(\text{PO}_4)_2 \cdot 5\text{H}_2\text{O}$; and A. Reynoso, $\text{Zn}_3(\text{PO}_4)_2 \cdot 6\text{H}_2\text{O}$. L. J. Spencer's analyses of both hopeite and parahopeite correspond with $\text{Zn}_3(\text{PO}_4)_2 \cdot 4\text{H}_2\text{O}$. G. Cesaro believed that the formula $5\text{Zn}_3(\text{PO}_4)_2 \cdot 4\text{Zn}(\text{PO}_3)_2 \cdot 7\text{Zn}(\text{OH})_2 \cdot 21\text{H}_2\text{O}$ best

FIG. 52.—Solubility Curves of Zinc Oxide in Phosphoric Acid.

(37°) there is a quadruple point where the tetrahydrated normal salt is in equilibrium with trihydrated hydrophosphate, $\text{ZnHPO}_4 \cdot 3\text{H}_2\text{O}$; there is another quadruple point at B (25°), where the latter phase is in equilibrium with the dihydrated dihydrophosphate, $\text{Zn}(\text{H}_2\text{PO}_4)_2 \cdot 2\text{H}_2\text{O}$. The monohydrated hydrophosphate, $\text{ZnHPO}_4 \cdot \text{H}_2\text{O}$, appears at 37° but not at 25°; and the quadruple points B

represents L. J. Spencer's analyses, but allowing for the impurities present in the native samples, the formula $\text{Zn}_3(\text{PO}_4)_2 \cdot 4\text{H}_2\text{O}$ best represents the composition of hopeite and parahopeite. N. E. Eberly, C. V. Gross, and W. S. Crowell studied the ternary system $\text{ZnO} - \text{P}_2\text{O}_5 - \text{H}_2\text{O}$ at 25° and 37° as far as 55 per cent. P_2O_5 . Their results are summarized in Fig. 52, where the dotted line refers to 37° and the other lines to 25°. The first branch of the curve represents the solubility of tetrahydrated zinc orthophosphate, $\text{Zn}_3(\text{PO}_4)_2 \cdot 4\text{H}_2\text{O}$, in phosphoric acid, and the position for the curve 37° shows that the solubility decreases as the temp. rises. At A (25°) or A'

and B_2 represent this phase in equilibrium respectively with the trihydrated hydrophosphate and the dihydrated dihydrophosphate.

A. de Schulten prepared anhydrous zinc orthophosphate by melting together a mixture of the hydrated salt with zinc chloride, or by heating in a sealed tube at 250° , a mixture of hydrated zinc orthophosphate with a conc. soln. of zinc chloride. F. Stromeyer made **cadmium orthophosphate** by adding to a soln. of a cadmium salt sodium hydrophosphate, A. de Schulten used normal sodium phosphate; and A. Reynoso prepared the orthophosphate by heating the pyrophosphate with water in a sealed tube at 280° – 300° for 5–6 hrs.

According to A. de Schulten, the **crystals** of anhydrous zinc orthophosphate are rhombic prisms. Hopeite was found by L. J. Spencer to occur usually in aggregates of acicular crystals, or in lamellæ. The crystals are rhombic bipyramids with axial ratios $a:b:c=0.5786:1:0.4753$, and A. de Schulten found the axial ratios with the artificial crystals to be $a:b:c=0.5759:1:0.4759$. L. J. Spencer stated that the imperfect crystals of parahopeite which were available are probably triclinic. N. E. Eberly and co-workers described the crystals of the tetrahydrate as "shining rhombic plates." The **specific gravity** of anhydrous zinc phosphate was found by A. de Schulten to be 3.998 at 15° ; and L. J. Spencer gave 3.04 for the sp. gr. of α -hopeite, 3.03 for β -hopeite; J. D. Dana gave 2.76–2.85 for hopeite; and A. de Schulten gave 3.109 for the artificial crystals. The **hardness** of hopeite is between 2.5 and 3.25 on Mohs' scale; that of parahopeite is 3.75.

A. de Schulten found that zinc orthophosphate melts at a bright red heat; and F. Stromeyer found cadmium orthophosphate melts to a colourless glass at a white heat. When α -hopeite is heated to 105° , it becomes opaque, while β -hopeite becomes opaque at 140° ; and parahopeite becomes white at 163° . The percentage loss of water at different temp. was found by L. J. Spencer to be:

	114°	135°	163°	180°	203°	233°	240°	290°
α -hopeite	5.2	8.5	—	9.8	10.1	—	14.9	15.8
β -hopeite	2.5	7.9	—	11.1	11.7	—	13.3	15.8
Parahopeite	—	—	1.9	—	11.6	15.5	—	—

Curves are plotted from these results in Fig. 53. According to L. J. Spencer, the **double refraction** of both varieties of hopeite is negative, that of parahopeite is positive; the axial angle of α -hopeite is 58.5° , and that of β -hopeite, 32.5° . The mean **index of refraction** of hopeite is 1.60, that of parahopeite is 1.62. A. des Cloiseaux gives for the index of refraction $\mu_\beta=1.471$ for Na-light, and 1.469 for red light; G. Cesaro gave 1.6 for Na-light, and he found $\gamma-\alpha=0.0115$; $\gamma-\beta=0.0022$; and $\beta-\alpha=0.0093$. E. Goldstein studied the **cathodophosphorescence** of cadmium phosphate; and E. L. Nichols, the brightness of the luminescence of the same salt.

Anhydrous zinc orthophosphate was found by A. de Schulten to be but slowly soluble in dil. acetic acid; and the hydrated phosphate was found by R. Schindler to be "insoluble" in water, easily soluble in dil. acids, and soluble in aq. ammonia, ammonium carbonate, sulphate, or nitrate; according to G. C. Stone, the solubility of zinc orthophosphate in an ammoniacal soln. of ammonium chloride distinguishes it from the corresponding salts of cadmium and magnesium. Zinc orthophosphate was found by W. Skey to give crystalline compounds with the corresponding phosphates of cobalt and nickel. F. Stromeyer also stated that cadmium orthophosphate is "insoluble" in water. C. Immerwahr measured the very sparing solubilities of zinc and cadmium phosphates in water. A. Colson found that the speed of decomposition of zinc orthophosphate by hydrogen sulphide, at a constant temp., is proportional to the square of the press. of the

FIG. 53.—Dehydration Curves of Hopeite and Parahopeite.

gas, but at low press. the absorption is rather slower. The speed of the reaction is twice as fast at 160° as at 100° .

L. J. Spencer reported that crystals of the basic zinc orthophosphate, $4\text{ZnO} \cdot \text{P}_2\text{O}_5 \cdot \text{H}_2\text{O}$, or $\text{Zn}_3(\text{PO}_4)_2 \cdot \text{Zn}(\text{OH})_2$, or $\text{Zn}_2(\text{OH})\text{PO}_4$, occurs as a mineral, *tarbuttite*, at Brocken Hill (N.-W. Rhodesia). The crystals are triclinic pinacoids, with the axial ratios $a:b:c=0.9583:1:1.3204$, and $\alpha=102^\circ 37'$, $\beta=123^\circ 52'$, and $\gamma=87^\circ 25'$. *Tarbuttite* has a composition analogous with *adamite*, the corresponding arsenate, but the two minerals are not isomorphous. The crystals have a strong negative double refraction; and the indices of refraction are 1.704 and 1.668. The sp. gr. of the colourless crystals is 4.15, and of the yellow crystals 4.12; and the hardness is 3.75. T. L. Walker and A. L. Parsons reported *spencerite*, $\text{Zn}_3(\text{PO}_4)_2 \cdot \text{Zn}(\text{OH})_2 \cdot 3\text{H}_2\text{O}$.

C. F. Wenzel dissolved zinc carbonate or phosphate or the metal in an excess of phosphoric acid, and on evaporation, obtained a gum-like mass which readily fused to a transparent glass. If a little alkali be added to the aq. soln., normal zinc phosphate is deposited. T. Graham prepared lamellar crystals of **monohydrated zinc hydrophosphate**, $\text{ZnHPO}_4 \cdot \text{H}_2\text{O}$, by mixing soln. of 3 parts of zinc sulphate and of 4 parts of sodium hydrophosphate. Each dissolved in 32 parts of hot water. The zinc sulphate is here in excess; if the sodium hydrophosphate be in excess normal zinc phosphate is produced. The crystals do not lose water at 100° , but below 230° , they give off two-thirds of their combined water; and at a red heat, they fuse and lose all their water. W. Heintz could not confirm T. Graham's results. The conditions of equilibrium of the monohydrate at 37° , and of the trihydrate are illustrated by the curves of Fig. 52. N. E. Eberly, C. V. Gross, and W. S. Crowell found that the monohydrate forms small, hard, transparent needles with an extinction oblique to the long axis, and which are probably triclinic; while the trihydrate forms "sticky, thread-like crystals agglomerating into masses like cotton-wool. The optical properties could not be observed." When zinc dihydrophosphate is treated with water, W. Demel found that a white insoluble crystalline powder, $10\text{ZnO} \cdot 4\text{P}_2\text{O}_5 \cdot 10\text{H}_2\text{O}$, or possibly $2\text{Zn}_3(\text{PO}_4)_2 \cdot 4\text{ZnHPO}_4 \cdot 8\text{H}_2\text{O}$, is formed which loses 1.6 per cent. of water at 100° and 10.03 per cent. at 280° .

According to A. de Schulten, the acid phosphate $5\text{CdO} \cdot 2\text{P}_2\text{O}_5 \cdot 5\text{H}_2\text{O}$, or $\text{Cd}_3(\text{PO}_4)_2 \cdot 2\text{CdHPO}_4 \cdot 4\text{H}_2\text{O}$, is precipitated when a soln. of a cadmium salt is treated with ordinary sodium phosphate; the precipitate, at first amorphous, soon becomes crystalline. Good crystals were made by dissolving cadmium carbonate in 250 c.c. of phosphoric acid of sp. gr. 1.10, aided by heat, until a slight precipitate of cadmium phosphate is produced. The mixture is heated on a water-bath and slowly mixed with 500 c.c. of 3 per cent. aq. ammonia. The same compound is formed by heating cadmium dihydrophosphate to 100° . The prismatic crystals belong to the monoclinic system, and have the axial ratios $a:b:c=1.8965:1:0.5159$, and they are isomorphous with the corresponding manganese salt, the mineral *hureaulite*. The sp. gr. of the crystals ranges from 3.96–4.15; the double refraction is negative. The crystals lose their water at a red heat, and fuse at a white heat—the residue has the composition $5\text{CdO} \cdot 2\text{P}_2\text{O}_5$. According to A. de Schulten, by fusing cadmium chloride or bromide with normal cadmium phosphate, or the phosphate $\text{Cd}_3(\text{PO}_4)_2 \cdot 2\text{CdHPO}_4 \cdot 4\text{H}_2\text{O}$, and washing the product with water, prismatic or pyramidal crystals of **cadmium chloroapatite**, $3\text{Cd}_3(\text{PO}_4)_2 \cdot \text{CdCl}_2$, of sp. gr. 5.46 at 15° , or **cadmium bromoapatite**, $3\text{Cd}_3(\text{PO}_4)_2 \cdot \text{CdBr}_2$, remain undissolved.

W. Demel prepared **dihydrated zinc dihydrophosphate**, $\text{Zn}(\text{H}_2\text{PO}_4)_2 \cdot 2\text{H}_2\text{O}$, by dissolving zinc oxide in an excess of aq. phosphoric acid, 100 grms. of the acid dissolve 10 grms. of the oxide. The soln. on standing deposits triclinic crystals with axial ratios $a:b:c=1.6002:1:1.1393$. The diagram, Fig. 51, shows the conditions of equilibrium of this salt. The crystals are permanent in air, and lose up to 1.86 per cent. of water at 100° , and at the same time fuse at the edges. The compound is decomposed by water as indicated above. The crystals are stable in the presence of alcohol or ether; and dissolve in hydrochloric acid. A. de

Schulten evaporated at ordinary temp. a dil. soln. of phosphoric acid, sat. with $\text{Cd}_3(\text{PO}_4)_2 \cdot 2\text{CdHPO}_4 \cdot 4\text{H}_2\text{O}$, and obtained rhombic prisms of **dihydrated cadmium dihydrophosphate**, $\text{Cd}(\text{H}_2\text{PO}_4)_2 \cdot 2\text{H}_2\text{O}$. The crystals have a sp. gr. of 2.741 at 15° ; they lose their water of crystallization at 100° ; and they are decomposed by water re-forming $\text{Cd}_3(\text{PO}_4)_2 \cdot 2\text{CdHPO}_4 \cdot 4\text{H}_2\text{O}$.

When a hot soln. of zinc sulphate is mixed with an excess of ammonium phosphate, H. Debray showed that amorphous **ammonium zinc phosphate**, ZnNH_4PO_4 , is precipitated, and if kept in contact with the heated mother liquid for 10–15 mins., crystallization occurs. Advantage is taken of this in H. Tamm's process² for the gravimetric determination of zinc; the washed precipitate is ignited in an oxidizing atm., and the metal weighed as zinc pyrophosphate, $\text{Zn}_2\text{P}_2\text{O}_7$. The **monohydrated ammonium zinc phosphate**, $\text{ZnNH}_4\text{PO}_4 \cdot \text{H}_2\text{O}$, was obtained by A. Bette³ by adding ammonium phosphate, mixed with an excess of aq. ammonia, to a soln. of zinc sulphate, and digesting the mixture at ordinary temp. until the precipitate is crystalline, and the excess of ammonia has evaporated. The precipitate is washed, pressed between folds of filter paper, and dried. W. Heintz modified the procedure a little. If sodium phosphate is used instead of the ammonium salt, A. Bette found the washing of the precipitate is difficult. W. Heintz stated that the microscopic crystals are colourless rectangular plates; and A. Bette added that they are insoluble in water, but soluble in soln. of ammonia, and potassium or sodium hydroxide. H. Debray stated that by the spontaneous evaporation of an acidified soln. of zinc chloride and ammonium phosphate, insoluble crystals of **monohydrated ammonium zinc dihydrophosphate**, $\text{Zn}(\text{NH}_4\text{HPO}_4(\text{H}_2\text{PO}_4) \cdot \text{H}_2\text{O}$, are produced. H. Schweikert found that microscopic scales of a basic ammonium zinc phosphate, $6\text{ZnO} \cdot 8\text{NH}_3 \cdot 3\text{P}_2\text{O}_5 \cdot 4\text{H}_2\text{O}$, are produced when ammoniacal soln. of zinc sulphate and phosphoric acid are mixed and allowed to stand for some days. W. Heintz found the crystals of the same salt separate when the mixed soln. is exposed to the cold of a winter's day.

E. H. Miller and R. W. Page prepared monohydrated **ammonium cadmium phosphate**, $\text{CdNH}_4\text{PO}_4 \cdot \text{H}_2\text{O}$, by mixing a soln. of a cadmium salt with an aq. soln. of ammonium phosphate, and allowing the flocculent precipitate to stand until it becomes crystalline. S. Drewsen believes that $1\frac{1}{2}$ mols of water of crystallization are present. The salt is readily soluble in aq. ammonia and in acids; and when boiled with water, the salt loses water and ammonia and forms normal cadmium phosphate. The monohydrate can be dried at 100° – 103° without decomposition. E. H. Miller, M. Austin, and A. Carnot and P. M. Proromant recommend the process for the gravimetric determination of cadmium; the washed precipitate can be ignited to cadmium pyrophosphate, $\text{Cd}_2\text{P}_2\text{O}_7$, and weighed.

H. Grandeau, and L. Ouvrard dissolved zinc or cadmium oxide, or a salt of these metals in fused alkali pyro- or ortho-phosphate, with or without an alkali chloride, and, after slowly cooling the fused mass, and extracting the soluble salts with water, obtained as a residue **sodium zinc phosphate**, ZnNaPO_4 , of sp. gr. 3.3 at 20° ; similarly also with **potassium zinc phosphate**, ZnKPO_4 ; **sodium cadmium phosphate**, CdNaPO_4 , of sp. gr. 4.1 at 20° ; and **potassium cadmium phosphate**, CdKPO_4 , of sp. gr. 3.8 at 20° . The rhombic crystals are sparingly soluble in water and acetic acid, but are readily dissolved by dil. mineral acids. P. Glühmann also prepared sodium cadmium phosphate. L. Ouvrard also prepared cubic crystals of **disodium zinc phosphate**, $\text{Zn}(\text{Na}_2\text{PO}_4)_2$, of sp. gr. 2.8 at 20° ; and **disodium cadmium phosphate**, $\text{Cd}(\text{Na}_2\text{PO}_4)_2$, by dissolving zinc or cadmium oxide in an excess of sodium pyrophosphate.

F. Stromeyer⁴ prepared gelatinous **zinc pyrophosphate**, $\text{Zn}_2\text{P}_2\text{O}_7$, by precipitation from a zinc salt soln. with sodium pyrophosphate. The gelatinous precipitate shrinks considerably on drying, and A. Schwarzenberg found that if it be suspended in water, and sulphur dioxide passed through the liquid, the whole dissolves, and the soln., when boiled, deposits the salt as a crystalline powder. J. Müller made zinc pyrophosphate by treating insoluble potassium metaphosphate

with a sat. soln. of zinc sulphate at 70° for 4 days; and by the prolonged action of a soln. of zinc sulphate on zinc triphosphate. As indicated above, zinc or cadmium pyrophosphate is obtained by calcining ammonium zinc or cadmium pyrophosphate. A. Schwarzenberg obtained **cadmium pyrophosphate**, $\text{Cd}_2\text{P}_2\text{O}_7$, by the action of a soln. of sodium pyrophosphate on a soln. of a cadmium salt, and crystalline plates may be obtained by the sulphur dioxide treatment employed for the zinc salt. A. de Schulten obtained it by fusing normal cadmium phosphate with cadmium bromide.

According to A. Schwarzenberg, the crystalline salt at 100° retains the eq. of $1\frac{1}{2}$ mols of water, and, according to C. N. Pahl, 5 mols. Crystalline cadmium pyrophosphate at 100° retains the eq. of 2 mols of water; F. W. Clarke gave 3.7556 for the sp. gr. of the zinc salt at 23° ; and A. de Schulten, 4.965 at 15° for the cadmium salt. According to P. Glühmann, cadmium pyrophosphate sinters without melting when heated to redness; and, according to A. Carnot and P. M. Proromant, the salt is not volatile at a red heat, but melts at a bright red heat. A. Schwarzenberg found that both the amorphous and crystalline zinc or cadmium pyrophosphates are soluble in acids, in potassium hydroxide lye, and in aq. ammonia. Alcohol precipitates a syrupy mass from the ammoniacal soln. G. von Knorre found zinc pyrophosphate is insoluble in acetic acid. J. H. Gladstone found that zinc or cadmium pyrophosphate dissolves in an excess of a soln. of sodium pyrophosphate; and F. Stromeyer, that when boiled with a soln. of sodium hydrophosphate, zinc pyrophosphate forms zinc dihydrophosphate and sodium pyrophosphate. P. Glühmann found calcined cadmium pyrophosphate is almost insoluble in acids, and is very sparingly soluble in cold water, but more soluble in hot water. According to A. Reynoso, when heated with water in a sealed tube at 280° – 300° for 5–6 hrs., it decomposes into a soln. of an acid phosphate, and crystals of the normal phosphate. Similar results were obtained with cadmium pyrophosphate. According to A. Schwarzenberg, when zinc or cadmium pyrophosphate is calcined in a stream of hydrogen, a sublimate of metal and phosphoric acid is formed, some phosphine is produced, and a white mixture of phosphoric acid and metal remains.

A. Bette obtained **zinc amino-pyrophosphate**, $3\text{Zn}_2\text{P}_2\text{O}_7 \cdot 4\text{NH}_3 \cdot 9\text{H}_2\text{O}$, by mixing a soln. of zinc chloride with enough ammonium chloride to prevent precipitation by ammonia, and then adding aq. ammonia, and a soln. of sodium pyrophosphate. The flocculent precipitate is washed until the runnings no longer give a turbidity with a soln. of silver nitrate, pressed between filter paper, and dried. According to C. N. Pahl, the solubility of zinc pyrophosphate in a soln. of sodium pyrophosphate appears to be greatest at 60° or 70° . K. A. Wallroth made **sodium zinc pyrophosphate**, $\text{ZnNa}_2\text{P}_2\text{O}_7$, and **sodium cadmium pyrophosphate**, $\text{CdNa}_2\text{P}_2\text{O}_7$, in white crystals by fusing the respective oxides in microcosmic salt at a bright red heat. The cold mass is leached with water and then with dil. hydrochloric acid. A. Wiesler made crystals of sodium zinc pyrophosphate by the action of zinc acetate on sodium trimetaphosphate. The crystals swell at a dull red heat, and fuse to a glass at bright redness. G. von Knorre obtained similar results. C. N. Pahl reported that hydrated $\text{ZnNa}_2\text{P}_2\text{O}_7$ could be obtained with $2\frac{1}{2}$ mols of water by adding water to the syrupy liquid obtained by the spontaneous evaporation of a soln. of zinc pyrophosphate in one of sodium pyrophosphate; with 3 and $3\frac{1}{2}$ mols of water of hydration by evaporating the soln. respectively at 50° and 60° ; the latter also as a crystalline powder by adding alcohol to the soln. The salt with 8 mols of water was obtained in prismatic crystals by evaporation at 30° . He also prepared long prismatic crystals of $3\text{Na}_4\text{P}_2\text{O}_7 \cdot \text{Zn}_2\text{P}_2\text{O}_7 \cdot 24\text{H}_2\text{O}$ from the syrupy liquid obtained by the spontaneous evaporation of an aq. soln. of zinc and sodium pyrophosphates. C. N. Pahl also obtained small prisms of $\text{Na}_4\text{P}_2\text{O}_7 \cdot 4\text{Zn}_2\text{P}_2\text{O}_7 \cdot 12\text{H}_2\text{O}$ from a soln. of zinc pyrophosphate in one of sodium pyrophosphate prepared at 60° – 70° ; and if prepared at 70° – 80° , $4\text{Na}_4\text{P}_2\text{O}_7 \cdot 5\text{Zn}_2\text{P}_2\text{O}_7 \cdot 20\text{H}_2\text{O}$. C. N. Pahl prepared $\text{Na}_2\text{CdP}_2\text{O}_7$ by adding cadmium chloride to a soln. of sodium pyrophosphate until the precipitate is no longer dissolved. The evaporation of the filtered soln. furnishes

prismatic crystals which melt at a red heat, and are insoluble in water. L. Ouvrard prepared **potassium zinc pyrophosphate**, $K_2ZnP_2O_7$, by melting together zinc oxide and potassium metaphosphate, or zinc phosphate and potassium chloride, and leaching out the soluble matter with water from the cooled salt. The crystals melt when heated, and they readily dissolve in acids. C. N. Pahl reported the formation of imperfect crystals of $4K_4P_2O_7 \cdot 5Cd_2P_2O_7 \cdot 20H_2O$ by a process similar to that employed for the corresponding sodium compound. L. Ouvrard prepared **potassium cadmium pyrophosphate**, $CdK_2P_2O_7$, in a similar manner.

J. J. Berzelius⁵ prepared glassy zinc metaphosphate by burning zinc sulphophosphide, ZnP_3S_2 . The product is soluble in water, and is sometimes regarded as **zinc dimetaphosphate**, ZnP_2O_6 , which A. Glatzel made by the action of potassium dimetaphosphate on a soln. of zinc chloride; B. Reinitzer and H. Goldschmidt by the action of zinc on phosphoryl chloride: $9Zn + 4POCl_3 = 6ZnCl_2 + 3ZnO + P_4O_{10}$, and $4ZnO + 2POCl_3 = ZnP_2O_6 + 3ZnCl_2$, which proceeds slowly at ordinary temp., or more rapidly at 100° ; and T. Fleitmann by evaporating zinc oxide, or a zinc salt of a volatile acid, with an excess of phosphoric acid, and heating the product to 350° . T. Fleitmann also made crystals of the *tetrahydrate*, $ZnP_2O_6 \cdot 4H_2O$, by mixing a soln. of ammonium dimetaphosphate with an excess of zinc chloride. The compound melts to a clear glass at a strong red heat, and it is decomposed by boiling with sulphuric acid. J. F. Persoz, and T. Fleitmann made what may have been **cadmium dimetaphosphate**, CdP_2O_6 , by mixing cadmium nitrate first with metaphosphoric acid, and then with aq. ammonia in which menstruum the precipitate dissolves, but separates again when the soln. is exposed to air. A. Glatzel obtained a white crystalline powder of the trihydrate $CdP_2O_6 \cdot 3H_2O$, by the action of ammonium or alkali dimetaphosphate on a soln. of cadmium sulphate. The water is lost at 150° without otherwise changing the salt, but an alteration occurs at a higher temp. The salt melts at a red heat, and when slowly cooled forms the tetrametaphosphate. 100 parts of water dissolve 3.13 parts of the salt. Both the cadmium and zinc salts are scarcely attacked by acids other than sulphuric acid; and are easily decomposed by molten sodium carbonate, forming sodium dimetaphosphate.

A. Bette obtained a white precipitate which soon coagulated to a resinous mass, and dried to a white powder by mixing ammoniacal soln. of zinc sulphate and vitreous sodium phosphate. The dry precipitate has 6.50 per cent. NH_3 , 46.45 ZnO , 33.68 P_2O_5 , and 13.37 H_2O , and it was supposed to be a mixture of phosphoric acid with a double phosphate of zinc and ammonium. A. Glatzel prepared **tetrahydrated ammonium zinc dimetaphosphate**, $(NH_4)_2ZnP_4O_{12} \cdot 4H_2O$, by treating zinc dimetaphosphate with an aq. soln. of ammonium chloride. It gives off ammonia at 200° , and most of the phosphoric oxide may be volatilized by prolonged heating. The salt also melts to a colourless glass; and it is decomposed by sulphuric acid. 100 parts of water dissolve 1.43 parts of the salt. A. Glatzel prepared **trihydrated ammonium cadmium dimetaphosphate**, $(NH_4)_2CdP_4O_{12} \cdot 3H_2O$, in white granules by the action of ammonium chloride on cadmium dimetaphosphate, or of ammonium dimetaphosphate on cadmium chloride. Two-thirds of the water are lost at 150° , and all at 200° without change in its constitution; it dissolves readily in acids. The compound loses ammonia when heated above 200° , and melts to a glass at a bright red heat. The glass is slowly decomposed by boiling acids, and rapidly by fused sodium carbonate.

G. Tammann reported that he had prepared **zinc trimetaphosphate**, $Zn_3(P_3O_9)_2 \cdot 9H_2O$, by mixing sodium trimetaphosphate with zinc chloride or sulphate. The precipitate separates slowly; 0.1 gm. dissolves in a litre of water at 20° ; and it melts to a glass at a dark red heat. A. Wiesler, however, could get only the pyrophosphate; nor did G. von Knorre succeed in verifying G. Tammann's conclusion. T. Fleitmann and W. Henneberg made **sodium zinc trimetaphosphate**, $Zn_2Na_2(P_3O_9)_2$; and A. Wiesler reported that **sodium cadmium trimetaphosphate**, $Na_4Cd(P_3O_9)_2 \cdot 4H_2O$, is obtained as a flocculent precipitate by mixing 10 grms. of sodium trimetaphosphate with a conc. soln. of 8 grms. of cadmium iodide, and

precipitating with alcohol. It is sparingly soluble in water and insoluble in alcohol.

A. Glatzel prepared **zinc tetrametaphosphate**, $\text{Zn}_2\text{P}_4\text{O}_{12}$, by evaporating a soln. of zinc oxide in one per cent. excess of phosphoric acid, heating the dry mass to redness, and slowly cooling. The powdered mass is washed with cold water. The salt is decomposed by fusion with sodium carbonate; it is soluble in nitric acid; dissolved by boiling sulphuric acid; and forms tetrametaphosphoric acid and zinc sulphide when treated with hydrogen sulphide. The **decahydrated zinc tetrametaphosphate**, $\text{Zn}_2\text{P}_4\text{O}_{12} \cdot 10\text{H}_2\text{O}$, separates in white crystals from dil. soln. of alkali tetrametaphosphate and zinc salts. Part of the water is lost at 100° , and all at 150° . It melts to a clear glass at a red heat; 1.818 parts of the salt dissolve 100 parts of water; and it is decomposed by boiling acids. A. Glatzel prepared **cadmium tetrametaphosphate**, $\text{Cd}_2\text{P}_4\text{O}_{12}$, and **decahydrated cadmium tetrametaphosphate**, $\text{Cd}_2\text{P}_4\text{O}_{12} \cdot 10\text{H}_2\text{O}$, in a similar manner. T. Fleitmann found that the former is easily decomposed by a soln. of sodium sulphide. A. Glatzel prepared colourless crystals of **hexahydrated potassium zinc tetrametaphosphate**, $\text{ZnK}_2\text{P}_4\text{O}_{12} \cdot 6\text{H}_2\text{O}$, by the action of potassium chloride on a soln. of zinc dimetaphosphate, and when heated to dull redness, the water is lost and the anhydrous salt is formed without change in the constitution. The salt melts at a strong red heat, and forms on cooling an opaque mass without any dimetaphosphate. It is decomposed by boiling sulphuric acid; and 1.14 parts of the salt dissolve in 100 parts of water. He also prepared in a similar way, **trihydrated potassium cadmium tetrametaphosphate**, $\text{CdK}_2\text{P}_4\text{O}_{12} \cdot 3\text{H}_2\text{O}$, 0.74 part of which dissolves in 100 parts of water; **hexahydrated sodium zinc tetrametaphosphate**, $\text{Na}_2\text{ZnP}_4\text{O}_{12} \cdot 6\text{H}_2\text{O}$, and **trihydrated sodium cadmium tetrametaphosphate**, $\text{Na}_2\text{CdP}_4\text{O}_{12} \cdot 3\text{H}_2\text{O}$, which is insoluble in water and more easily decomposed by water than the potassium salt. G. Tammann also reported regular crystals of **sodium zinc octometaphosphate**, $\text{Na}_2\text{Zn}_3\text{P}_8\text{O}_{24}$, as a result of melting a mol of sodium ammonium phosphate with a mol of zinc sulphate. It is insoluble in most acids, but soluble in conc. sulphuric acid; and produces a grey film when treated with alkali sulphides.

J. Müller⁶ obtained what was possibly **zinc triphosphate**, $\text{Zn}_5(\text{P}_3\text{O}_{10})_2$, by treating insoluble sodium metaphosphate with a sat. soln. of zinc sulphate at 70° , for a long time, and he made **cadmium triphosphate**, $\text{Cd}_5(\text{P}_3\text{O}_{10})_2$, in a similar way; and P. Glühmann made it by treating an aq. soln. of sodium triphosphate with a soln. of cadmium sulphate. The product may be a mixture of tetraphosphate and pyrophosphate because the reactions are characteristic of pyrophosphates. It sinters without melting at a red heat, and it then becomes insoluble in acids. The salt is insoluble in water. F. Schwarz prepared prismatic, possibly triclinic crystals of hydrated **sodium zinc triphosphate**, $\text{NaZn}_2\text{P}_3\text{O}_{10} \cdot 9\frac{1}{2}\text{H}_2\text{O}$, by the action of a zinc salt on sodium triphosphate. P. Glühmann made **dodecahydrated sodium cadmium triphosphate**, $\text{Na}_3\text{CdP}_3\text{O}_{10} \cdot 12\text{H}_2\text{O}$, from a cold sat. soln. of cadmium sulphate and the calculated quantity of sodium triphosphate. The mineral *arakawaite* from Arakawa Mine, Akita, Japan, was described by Y. Wakabayashi and K. Komada as a **zinc copper phosphate**, $(\text{Cu}, \text{Zn})_6\text{P}_2\text{O}_{11} \cdot 7\text{H}_2\text{O}$. The dark bluish-green crystals belong to the monoclinic system, and have the axial ratios $a:b:c=0.7497:1:1.0245$, and $\beta=70^\circ 30'$. The sp. gr. is 3.09; the hardness $3\frac{1}{2}$; the optic axial angle $2\gamma=38^\circ 30'$; the indices of refraction $\alpha=1.618$, $\beta=1.622$, and $\gamma=1.658$; and the optical character positive.

§ 21. Alloys and Intermetallic Compounds of the Calcium and Zinc Families

The alloys of calcium and of barium or strontium with the alkali metals have not been investigated. H. Caron¹ obtained an alloy of sodium and calcium by melting in a well-closed iron crucible an excess of sodium with calcium chloride. When the resulting product is heated in an iron retort, the sodium may be all distilled off. W. Moldenhauer and J. Anderson prepared an alloy of calcium and potassium. A review of our present knowledge of the binary alloys of the alkali, copper, calcium, and zinc families is indicated in Table VI, which shows by a hyphen (—) that the

alloys have not been investigated; a cipher means that no compound is formed; and a C means that one or more compounds are known. For convenience, mercury has been included in the summary.

Sodium, potassium, and lithium do not unite with magnesium to form a compound. T. L. Phipson² made a ductile alloy of magnesium and sodium which decomposed water at ordinary temp. J. Parkinson found the two elements unite at a red heat without incandescence, and form a silvery white alloy which readily decomposes water when the sodium dissolves, and magnesium metal remains. Mixtures of magnesium and sodium separate into two layers at 638° one with between 2 and 97 per cent. of sodium, and the other with up to 3 per cent. of magnesium, Fig. 56. According to T. L. Phipson, magnesium alloys with potassium to form a ductile alloy which decomposes water at ordinary temp.; but D. P. Smith showed that the two elements are almost immiscible when melted, and that the m.p. of neither element is much affected by small additions of the other, Fig. 55. The behaviour of potassium resembles that of sodium towards magnesium, but the solubility of potassium is even less than that of sodium in magnesium. G. Masing and G. Tammann showed lithium and magnesium form two series of mixed crystals above 95 per cent., and below 85 per cent. magnesium, Fig. 54.

FIG. 54.—Fusion Curves of Lithium-Magnesium Alloys.

FIG. 55.—Fusion Curve of Potassium-Magnesium Alloys.

FIG. 56.—Fusion Curve of Sodium-Zinc Alloys.

Both sodium and potassium appear to unite with zinc to form binary compounds, Figs. 56–57. J. L. Gay Lussac and L. J. Thénard,³ and G. S. Sérullas made an alloy of potassium and zinc. The brittle mass melted at a red heat; oxidized readily in air; and decomposed water, especially in the presence of dil. acids. J. L. Gay Lussac and L. J. Thénard also made an alloy of sodium and zinc. Qualitative experiments on the zinc-sodium alloy were also made by R. Rieth and F. Beilstein,

F. Haber and M. Sack, H. Rose, and C. T. Heycock and F. H. Neville. L. Hulin made the alloy by forcing a stream of sodium under press. into a bath of molten zinc. F. L. Sonnenschein, C. H. Mathewson, N. S. Kurnakoff and A. N. Kusnetzoff studied the alloys of cadmium and sodium; and D. P. Smith those of potassium and cadmium. The general character of the equilibrium curves is shown in Figs. 56 and 57. Certain arrests in the cooling curve are interpreted to mean chemical combination. The provisional formulæ of **potassium zincide** is KZn_{11} or $_{12}$, and of **sodium zincide**, NaZn_{11} or $_{12}$, as advocated by D. P. Smith and C. H. Mathewson. Potassium and cadmium alloys give a f.p. curve rising to a maximum at 473° , corresponding with **potassium cadmide**, $\text{Cd}_{11} \text{ } _{12}\text{K}$, and then falling to a horizontal line at 68° with between 17 and 99 atomic per cent. of potassium. Mixtures represented by points on this line separate into two layers—one rich in potassium, and the other rich in cadmium. There is a doubt whether a slight singularity in the curve between the horizontal line and the maximum for KCd_{11} or $_{12}$ represents an experimental error or the formation of a compound Cd_7K . R. Kremann and A. Mehr measured the e.m.f. of zinc alloys with potassium for the cell $\text{Zn} | \text{KCl}_{\text{pyridine}} | \text{K} - \text{Zn}_{\text{alloy}}$; and similarly also for $\text{Cd} | \text{KCl}_{\text{pyridine}} | \text{K} - \text{Zn}_{\text{alloy}}$. G. Tammann measured the chemical activity of the potassium alloys with cadmium and with zinc. The curve with sodium and cadmium was shown by N. S. Kurnakoff and A. N. Kusnetzoff to have two maxima corresponding with **sodium cadmides** represented by cubic crystals of Cd_4Na or Cd_5Na freezing at 363° , and octahedral crystals of Cd_2Na freezing at 385° , and with a sp. gr. 5.669 at $20^\circ/4^\circ$. There is a horizontal line at 330° , with between 58 and 70 atomic per cent. of sodium. The depression in the f.p. of cadmium observed by G. Tammann, and by C. T. Heycock and F. H. Neville, is too small to appear on the scale of Fig. 59. W. Biltz and C. Haase found 5.650 for the sp. gr. of sodium diacadmide at $25^\circ/4^\circ$; and 7.069 for that of the pentacadmide. They also measured the heats of formation of these compounds. According to G. D. Roos, the heat of fusion of sodium cadmide, NaCd_4 , is 16.9

FIG. 57.—Fusion Curve of Potassium-Zinc Alloys.

FIG. 58.—Fusion Curve of Lithium-Cadmium Alloys.

FIG. 59.—Fusion Curve of Sodium-Cadmium Alloys.

Cals. per gram, and of Cd_2Na , 22.8 Cals. per gram. The heats of formation of the two compounds are respectively 60.6 ± 3.5 Cals. per mol, and 30.8 ± 1.6 Cals.

per mol. There is also estimated to be a 10 per cent. dissociation on melting NaCd_4 and 5.5 per cent. dissociation on melting NaCd_2 . G. Tammann measured the chemical activity of sodium alloys with zinc and with cadmium. According to G. Masing and G. Tammann, lithium probably forms two **lithium cadmides**, namely, LiCd , freezing at 505° ; and LiCd_2 , freezing at 541° . The equilibrium diagram is shown in Fig. 58. R. Kremann and P. von Reiningshaus studied the e.m.f. of alloys of sodium with zinc and cadmium.

P. Lebeau⁴ has prepared alloys of copper and beryllium by heating a mixture of the two oxides in an electric furnace. The alloy with 1.32 per cent. of beryllium is golden-yellow, and that with 5 per cent. of this metal is yellow, easily polished, does not oxidize in air, and dissolves with difficulty in nitric acid. The alloy with 10 per cent. of beryllium is pale yellow, almost white. The alloys give a f.p. curve, Fig. 61, which shows that the m.p. of copper (1083°) is depressed rapidly to 865° by the addition of beryllium, and α -solid soln. containing up to 10.5 atomic per cent. of beryllium are formed; the f.p. curve then changes its direction and falls less rapidly down to a eutectic at about 840° with 27.3 atomic per cent. of beryllium. The curve then rises to a point of inflection at about 910° , and there is a break at 938° . There is a point of inflection corresponding with **beryllium cupride**, Cu_2Be ,

FIG. 60.—Fusion Curve of Potassium-Cadmium Alloys.

FIG. 61.—Fusion Curve of Beryllium-Copper Alloys.

FIG. 62.—Fusion Curve of Beryllium-Silver Alloys.

and breaks at about 910° and 938° . The curve then rises to a point of inflection at 1206° corresponding with CuBe_3 . β -solid soln. extend from 23.5 to 45.5 atomic per cent. of beryllium; γ -solid soln. from 46.5 to 49 atomic per cent. of beryllium; and δ -solid soln. from 70 to 75 atomic per cent. of beryllium. A mixture of β - and γ -solid soln. extends from 45.5 to 46.5 atomic per cent. of beryllium, and a mixture of γ - and δ -solid soln. from 49 to 70 atomic per cent. of beryllium. The f.p. curve of silver-beryllium alloys is much simpler than is the case with the copper-beryllium alloys. G. Oosterheld found a eutectic at 878° with about 15.3 atomic per cent. of beryllium, and the curve rises to a point of inflection at 92.6 atomic per cent. of beryllium when there is a break representing a compound of unknown composition— AgBe_n , Fig. 62.

J. Parkinson⁵ prepared an alloy of copper and magnesium by putting magnesium under molten copper, covered with a layer of charcoal; H. N. Warren and others made an alloy by melting the two metals under borax, magnesium, sodium, or potassium chloride, or calcium fluoride. R. E. Slade reduced a mixture of magnesia and carbon in an electric furnace, and absorbed the vapour of magnesium by copper; A. Schmidt, and K. Seubert and A. Schmidt heated a mixture of cuprous chloride and magnesium filings; J. Bogusky electrolyzed fused cryolite with copper electrodes; D. S. Ashbrook electrolyzed mixed soln. acidified with nitric acid—A. Siemens found soln. of the sulphates do not give an alloy. M. Rietz and M. Herold electrolyzed a mixed soln. of a magnesium salt of an organic acid and cupric cyanide. The f.p. diagram of copper and magnesium, Fig. 63, has three eutectics, one with about

9 per cent. of magnesium, melting at about 480° ; one with about 31 per cent. of magnesium, melting at about 552° ; and one with about 70 per cent. of magnesium, melting at about 485° . According to R. Sahmen, the maximum at 797° corresponds with **magnesium cupride**, Cu_2Mg ; and that at 570° with CuMg_2 . O. Boudouard's compound CuMg has no existence. L. Guillet found that alloys with up to 4 per cent. of magnesium are malleable; J. Parkinson's report of the brittleness of the alloys is based on experiments with impure materials. M. Mouchel found the alloys have great mechanical strength, and a small electrical resistance; and L. Aitcheson tested the mechanical properties of the 3 and 13 per cent. copper alloys. G. Tammann and K. Dahl also studied the brittleness of this compound. They observed no gliding planes in the crystals, and noted the compound becomes plastic 50° below its m.p. C. A. Kraus measured the electrical conductivity of magnesium dicupride and hemicupride. O. Boudouard noted the solubility of the alloys in dil. nitric acid; E. Beck, the fixation of nitrogen by the heated alloy; W. Jenge, and G. Tammann, the chemical activity; and R. Sahmen, the attack on porcelain by molten alloys with over 10 per cent. of magnesium.

J. Parkinson⁶ prepared an alloy of silver and magnesium. S. F. Schemtschuschny studied the f.p. curve, Fig. 64, and obtained a eutectic at 756° , and a maximum at 820° corresponding with **magnesium argentide**, AgMg , and there is a bend in the curve at 492° corresponding with the argentide AgMg_3 . There is a second eutectic at 469° . W. Smirnof and N. S. Kurnakoff stated that these two compounds form hylotropic phases, for they melt without decomposition. Silver

FIG. 63.—Fusion Curve of Magnesium-Copper Alloys.

FIG. 64.—Fusion Curve of Magnesium-Silver Alloys.

FIG. 65.—Fusion Curve of Magnesium-Gold Alloys.

forms solid soln. with about 28 at. per cent. of magnesium, and the compound AgMg forms solid soln. with 12 at. per cent. of silver, and 16 at. per cent. of magnesium. According to S. F. Schemtschuschny, the crystals of Mg_3Ag belong to the hexagonal system, and have axial ratios $a:c=1:0.6965$. W. Smirnof and N. S. Kurnakoff studied the hardness of the magnesium-silver alloys, and obtained a well-defined minimum corresponding with the compound Mg_3Ag ; at this point there is also a minimum in the electrical conductivity curve, and a maximum in the curve representing the temp. coeff. of the electrical resistance. There was also a sharp maximum in the conductivity curve corresponding with MgAg . K. Bornemann found that freshly cut surfaces of alloys with 57 to 70 at. per cent. of silver are yellow; the malleability of silver is lowered when alloyed with magnesium; and alloys rich in magnesium are brittle and decompose water more easily than silver alone. G. Tammann studied the chemical activity of the alloy.

Alloys of gold and magnesium were first made by J. Parkinson,⁷ and they were studied in detail by R. Vogel, and G. G. Urazoff. They were made by heating a mixture of the two metals in a graphite crucible under a layer of fused potassium chloride and calcium chloride. M. le Blanc and L. Bergmann observed the formation of the alloy when magnesium was heated with sodium hydroxide to 400° in a gold crucible. The fusion curve is shown in Fig. 65. There is a eutectic at 830° , and a maximum corresponding with the formation of **magnesium auride**, AuMg , between 1150° and 1160° ; a second eutectic occurs at 783° , and a second maximum

at 788° – 796° corresponding with AuMg_2 ; a third eutectic occurs at about 772° , and a third maximum between 818° and 830° , corresponding with AuMg_3 ; and a fourth eutectic occurs at about 576° . There is a break in the curve at 796° – 798° , corresponding with the formation of Au_2Mg_5 . Several solid soln. are formed. G. Tammann studied the chemical activity of the alloy. He argued that in a series of mixed crystals or in a mixture of definite chemical individuals the alloy behaves either as one component or as the other; thus the AuMg -alloy is as noble as gold, and the AuMg_2 -alloy is as easily attacked as magnesium.

Certain alloys of copper and zinc, used extensively in the arts and crafts, are called brasses; and certain alloys of copper and tin are likewise called bronzes. Copper is the predominant element in brasses and bronzes, and its primary function is to impart toughness and strength to the alloy. The additional elements modify the physical properties—m.p., tenacity, hardness, ductility, sp. gr., electrical resistance, etc.—in certain desired directions. By simply varying the proportions of zinc between 30 and 50 per cent., alloys may be obtained presenting such diverse qualities that the different members of the series appear to represent different metals. The history⁸ has been previously discussed; the term *asem* was employed in the third-century Egyptian papyri for an alloy of copper and tin. There is a chapter headed *De compositis brandisii* in the eighth-century book *Compositiones ad tingenda*, which deals with the manufacture of bronze, and this has been taken to show that the term bronze is derived from Brindes, a synonym for Brandusium (Brindisi), a town noted in Pliny's day for its bronze mirrors. There is, however, no general agreement as to the origin of the term *bronze*. The term *brass* seems to be derived from *braes*, an old English word for an alloy of tin and copper, and which later came to be used for alloys of zinc and copper. The old brasses resembled the modern metal in composition and analyses have been given by C. J. B. Karsten,⁹ C. C. T. F. Göbel, J. A. Phillips, and many others.

In a report:¹⁰ *The Nomenclature of Alloys*, it is recommended that the term *brass* be used as an abbreviation for the words "copper-zinc alloys containing over 50 per cent. of copper." If the alloy contains a third metal intentionally added, the name of that is applied as a prefix—e.g. an alloy with one per cent. of tin, 29 of zinc, and 70 of copper would be called *tin-brass*; and the so-called German silver, copper 50, zinc 25, and nickel 25, becomes *nickel-brass*. If additional metals are present, their names can be similarly prefixed, or the term *complex-brass* can be employed. The term *bronze* is likewise to be used as an abbreviation for "copper-tin alloys containing over 50 per cent. of copper." The presence of a third metal intentionally added is indicated as in the case of brass; and likewise for *complex-bronzes*.

There are many varieties of brass, and several have received special trade names. A brass suitable for rolling and drawing contains approximately 30 per cent. of zinc, and one rather less ductile has 33 per cent. of zinc; brass for naval work has about 37 per cent. of zinc and one per cent. of tin, it resists the corrosive action of sea-water rather better than ordinary brass, and it is harder. Lead is sometimes added to brass to facilitate its being turned or machined. Few brasses used for engineering work contain over 40 per cent. of zinc because of their low ductility. Table VII represents the composition of a number of varieties of brass.

Small quantities of iron harden and strengthen copper alloys, the use of ferro-manganese for the same purpose was patented by P. M. Parsons¹¹ in 1876. The alloys hardened by the addition of ferro-manganese ranged from the true brasses to the true bronzes of the gun-metal type. The manganese acts as a deoxidizer, and causes the iron to alloy more readily with the metal. If more manganese is used, it has a hardening and strengthening effect like iron, but not so pronounced. The alloy has a relatively high resistance to the corrosive influence of sea-water. Sand castings of *manganese brass* were found to be impracticable and the first castings were true bronzes fortified with a little manganese, but on account of the greater cost of tin these alloys were more expensive than brasses. P. M. Parsons later found that the addition of a little aluminium to the manganese brasses with 40 to 45 per cent. of zinc, enable sand castings to be made equal to, if not superior to, the more costly bronze, and, owing to a confusion in the use of terms, *manganese bronze*

was applied to both tin and zinc alloys. The best brands of manganese bronze on the market are in reality high-grade brasses. With 55 to 60 per cent. of copper and 40 to 45 per cent. of zinc with small amounts of tin, manganese, aluminium, etc., along with a hardener—usually iron—*e.g.* the U.S. Navy Department's specification manganese bronze contains: copper, 56–58 per cent.; zinc, 40–42 per cent.; and not more than 1.0 per cent. of tin, 0.5 per cent. of aluminium, 0.3 per cent. of manganese, and 0.10 per cent. of lead. Manganese bronzes of varying tensile strength and ductility can be obtained by varying the proportions of copper and zinc. There are two main varieties—one is used for rolling and drawing and contains no aluminium, and the other is used for sand castings and contains aluminium.

TABLE VII.—SOME COPPER-ZINC ALLOYS.

Alloy.	Zinc.	Copper.	Remarks.
Antifriction metal	85	5	Antimony, 10.
Foundry metal	75	—	Tin, 25.
Vaucher's bearing alloy	75	—	Tin, 18; Pb, 4.5; Sb, 2.5.
Manganese bronze	56–58	42–40	Al, Mn, Sn, and Pb, about 2
Mosaic gold	55–52	45–48	Bath metal has 45Zn, 55Cu.
Brazing solder	50	50	Other proportions are used.
Delta metal	43	55	Iron, 1 to 2.
Muntz metal	40	60	
Sterro-metal	38	60	Iron, 1 to 2.
Admiralty naval brass	37	62	Tin, 1.
Common brass	33	67	
Cartridge brass	30	70	
White metal	22	54	Nickel, 24.
German silver	20	50	Nickel, 30.
Dutch metal	20	80	Also Mannheim gold.
Similor	16.7	83.3	
Tombac	15.5	84.5	
Imitation yellow gold	15	85	Tin up to one per cent.
Prince's metal	14	86	
Oreide	10	90	
Red tombac	8	92	
Pinchbeck	6.4	93.6	
Viennese tombac	2.8	97.8	
Admiralty gun metal	2	98	Tin up to 10 per cent.
British coinage	1	95	Tin up 4 to per cent.
Imitation red gold	4	96	Tin up to one per cent.

The effect of *silver* and *gold* on brass has been studied by L. Guillet; of *aluminium*, by L. Guillet, O. Bauer, J. Czochralsky, W. Rosenhain, J. L. Haughton, and K. E. Bingham; of *manganese*, of *chromium*, of *magnesium*, of *cadmium*, and of *silicon*, by L. Guillet; of *antimony*, by J. Czochralsky; of *arsenic*, by R. T. Rolfe; of *iron*, by L. Guillet, F. Johnson, and O. Smalley; of *cobalt*, L. Guillet, and S. Pile; of *nickel*, by L. Guillet, and S. Pile; of *tin*, by L. Guillet, and W. Campbell, see *bronze*; of *lead*, by L. Guillet, and A. Kessner; of *phosphorus*, by A. Portevin; of *cerium*, by L. W. Spring; and of *sulphur*, by S. Pile.

In the older method of making brass, roasted calamine, or furnace calamine, mixed with charcoal and granulated copper, was heated in a crucible; and also zinc oxide was heated with copper and charcoal under similar conditions. Brass is usually made by fusing the two metals in a graphite crucible, the copper being placed above the zinc.¹² When copper is exposed to the vapour of zinc it is completely penetrated and brass is formed. The so-called Lyons gold lace was made by exposing rods of copper to the vapour of zinc and when the surface had been converted into brass, the rods were drawn into wire. When a copper coin is placed in a crucible above a mixture of charcoal and zinc oxide, and moderately ignited, the copper is converted into brass without spoiling the impression on the coin. P. Lebeau,¹³ and G. L. J. de Chalmot produced some brass by the action of zinc on cupric silicide, Cu₂Si; and B. Neumann, and F. von Kügelgen, by reducing a mixture of zinc

chloride and cupric oxide with calcium carbide. W. Spring, and G. Masing made alloys by compressing mixtures of the powdered elements. According to W. Meissner, when a soln. of copper sulphate in 20 parts of water is precipitated by zinc, the first black flakes which separate are an alloy of copper and zinc; and F. Mylius and O. Fromm also made similar observations. R. Böttger noted the formation of a film of brass when copper is dipped in a soln. of sodium zincate. H. Weiss, and O. H. Hudson studied the reciprocal penetration of zinc and copper at temp. below 419° . F. M. Raoult found that brass is formed when a copper plate in contact with a zinc wire is dipped in a soln. of zinc sulphate. F. Mylius and O. Fromm¹⁴ observed that a zinc anode in a soln. of a cupric salt is at first blackened owing to the formation of a copper-zinc alloy. C. B. Jacobs, W. D. Bancroft, K. Norden, J. L. R. Morgan, G. McP. Smith, S. P. Thompson, T. J. Baker, F. W. Croucher, L. Houllévine, F. Kunschert, S. O. Cowper-Coles, R. Namais, F. Sauerwald, F. Peters, A. L. Ferguson and E. G. Sturdevant, G. Langbein, J. Stark, F. Spitzer, etc., have studied the electrolytic deposition of brass from aq. soln. of zinc and copper salts. W. H. Walenn, working with an electro-brassing soln. containing potassium cyanide and ammonium tartrate, at a temp. a little above 0° , obtained nearly pure zinc on the cathode; as the temp. was raised, the deposit changed in tint, becoming silvery white, and then acquired a yellow colour. He suggested that M. Prat's new element *lavesium* is the silvery-white deposit. O. Meyer deposited brass from an alcoholic soln. of the two salts; and R. Lorenz, from fused cupric and zinc chlorides.

T. Svedberg prepared brown **colloidal brass**—brass methyl-alcosol by his process previously described—2. 23, 10. O. Ohmann made *brass wool*. M. R. Andrews found that the **X-radiograms** of zinc-copper alloys show three structures: those with 0.040 per cent. of zinc have the face-centred cubic lattice of copper; those with 40–50 per cent. of zinc have mixed face-centred and centred cubic lattices; those with 50–70 per cent. of zinc have a nearly pure centred cubic lattice; those with 70–80 per cent. of zinc have a mixture of the centred cubic lattice and another probably rhombohedral; those with 80–90 per cent. of zinc have almost the pure rhombohedral form; and those with 90–95 per cent. of zinc have a mixture of the rhombohedral and the hexagonal zinc lattices. E. C. Bain also studied the X-radiograms of these alloys.

Many copper-zinc alloys have been symbolized by chemical formulæ as if the mixtures were chemical individuals—e.g. F. C. Calvert and R. Johnson,¹⁵ J. H. Croockewit, T. Matsuda, R. Mallet, etc. E. S. Shepherd failed to find any clear evidence of the formation of definite compounds of copper and zinc, and he stated that all the alloys of these metals are solid soln. A. P. Laurie, W. Guertler, G. Charpy, M. Herschkowitsch, and T. J. Baker, from measurements of certain physical properties, inferred the existence of a **zinc cupride**, Cu_2Zn_3 , and possibly Cu_2Zn . The compound Cu_2Zn is probably formed at 905° , and Cu_2Zn_3 at 830° . There may be other compounds, but their composition has not been established. N. A. Puschin¹⁶ believes that in its alloys, copper behaves like a univalent element in the first group of the periodic table. The thermal and other properties of the copper-zinc alloys have been the subject of many investigations. The general f.p. curve is illustrated by Fig. 66, where $\alpha_{\text{liq.}}$ is employed as an abbreviation for a mixture of α -solid plus liquid; similarly for $\beta_{\text{liq.}}$; etc. The symbols α , β , γ , δ , ϵ , and η represent the six solid soln. of the two metals. The liquidus curve has six branches corresponding with the six solid phases represented by α , β , γ , δ , ϵ , and η . Alloys with less than 30 per cent. of zinc always contain the α -solid soln., and alloys with up to 37 per cent. of zinc may contain nothing but the α -phase, but with alloys over 30 per cent. zinc, the β -phase may also be present. The equilibrium conditions for these and other phases are indicated in the diagram. When a molten brass containing, say, 70 per cent. of copper is cooled the α -solid soln. separates out, the first portions are much richer in copper than the later portions, and the last portions to freeze out are richest in zinc, but are still within the range of the α -soln. The polished surface

of the solid metal shows under the microscope a number of primary red cores surrounded by the lighter coloured brass—the cores contain about 85 per cent. of copper, the lighter portions have about 65 per cent. of copper, so that the whole of the heterogeneous mass contains the α -solid soln. When this brass is annealed the cored structure disappears, because the zinc slowly diffuses from the parts where it is most conc. to the parts poorest in zinc. A molten brass with about 60 per cent. of copper furnishes both β - and α -solid soln. when it is cooled; when annealed between 400° and 470° , the β -solid soln. is gradually absorbed by the primary β -solid soln. An alloy containing 40 per cent. of zinc—Fig. 66—rapidly cooled from 880° , contains

FIG. 66.—Equilibrium Diagram of Copper-Zinc Alloys.

the β -phase; if annealed to 650° and rapidly cooled, it contains the solid phase α and β side by side; and if annealed at 400° , the solid contains the α and γ phases.

Brasses with the α -phase predominant are soft, with a high tensile strength and ductility; the appearance of the β -phase makes the brass harder, stronger, and less ductile. Expressing the percentage composition as a weight ratio—copper : zinc, typical commercial 70 : 30-brass or cartridge brass has a single homogeneous solid soln., the α -constituent. The alloy is very ductile, and can undergo severe cold-working without cracking, but cannot be rolled at a red heat without difficulty. In the 60 : 40-brass, the α -constituent is accompanied by the β -solid soln., which increases from zero to unity as the percentage of zinc increases from 36.5 to 46.5. The β -constituent is plastic at high temp., and moreover, the ratio of β : α increases with rise of temp., and the original proportion is restored on cooling. The plastic β -constituent enables brass to be rolled, stamped, or extracted at a red heat; and the product can be readily machined when cold. F. Johnson has made a special study of the effect of cold rolling on β -brass. L. Guillet and M. Ballay studied the effect of work—*écrouissage*—on the critical points of brass; and W. Fränkel and H. Becker, the speed of formation of α and β brasses.

The colour of the series of copper-zinc alloys has been studied by R. Mallet,¹⁷ T. Turner, H. Behrens, E. S. Shepherd, etc. Expressing the proportions as an atomic ratio Cu : Zn, R. Mallet reported :

Reddish-yellow.	Yellowish-red.	Pale yellow.	Deep yellow.	Silver-white.	Light grey.	Dark grey.
10:1 to 7:1	6:1 to 4:1	3:1	2:1 to 1:2	8:17 to 1:2	8:19 to 8:23	1:3 to 1:5

The colours of the copper-zinc alloys, with increasing proportions of zinc, pass from the yellowish-red of the 1 to 9 per cent. alloys to the yellow of the 20 to 30 per cent. alloys, the yellowish-red of the 50 per cent. alloys to the pinkish-grey of the 50 to 56 per cent. alloys, the silvery-white of the 58 to 66 per cent. alloys, to the bluish-grey of alloys with over 70 per cent. of zinc. The colour of the solid phases thus appears to be: α -phase (copper 100–63 per cent.), red; β -phase (54–51 per

cent.), reddish-yellow; γ -phase (40–30 per cent.), silvery-white; and ϵ -phase (20–13 per cent.), bluish-grey. O. Bauer and H. Arndt observed no liquation or segregation in brasses with 28 and 37 per cent. zinc. The **minute structure** has been studied by F. H. Storer, E. S. Shepherd, A. Portevin, G. Charpy, T. T. Cocking, F. Korber and P. J. H. Wieland, J. L. Haughton and K. E. Bingham, L. Révillon and P. Beauverie, F. Johnson, H. M. Brayton, J. S. G. Primrose, S. Pile, etc.; the **fracture** by R. Mallet, E. Maey, E. S. Shepherd, G. Charpy, etc. Further, G. D. Bengough and O. F. Hudson, F. Dörinckel and J. Trockels, H. Behrens, H. Moore and S. Beckinsale, P. Breuil, etc., have studied the effect of the annealing temp. on the grain-size of the metal. The effect of annealing and rolling on the **X-radiograms** of the brasses has been studied by S. Nishikawa and G. Asahara. The **specific gravity** was determined by R. Mallet, E. Maey, T. G. Bamford, E. S. Shepherd, R. Hennig, etc. R. H. Weber gave for the sp. gr. at $17^{\circ}/17^{\circ}$, for alloys with

	100	88.67	78.53	66.53	50.85	41.97	25.95	9.74	0% Cu
Sp. gr. . . .	8.997	8.700	8.573	8.444	8.235	8.128	7.744	7.272	7.024

A. Riche inferred the formation of a compound Cu_2Zn_3 from the brittleness and the sp. gr. curves of the copper-zinc alloys. R. H. Weber also inferred the formation of a compound CuZn from the sp. gr. curve. R. J. Anderson and E. G. Fahlman, and F. Johnson and W. G. Jones studied the linear shrinkage in casting brass. G. Tammann and K. Dahl found that while brass at ordinary temp. shows good gliding planes, it becomes plastic about 20° below the m.p. The **specific volume** has been determined by E. Maey, C. Upthegrove and W. C. Harbert, P. Braesco, and W. C. Roberts-Austen; the **hardness**, by H. Behrens, C. H. Desch, P. Ludwik, J. F. Springer, F. W. Harris, F. Auerbach, F. C. Calvert and R. Johnson, E. S. Sperry, A. Portevin, G. A. Dick, E. Maey, D. Meneghini, W. H. Bassett and C. H. Davis. Breaks in the hardness curve of the copper-zinc alloys led N. S. Kurnakoff and S. F. Schemtschuschny to infer the existence of a compound Cu_2Zn . G. Charpy and H. Behrens' observations on the microscopic structure and hardness of copper-zinc alloys led them to infer the formation of a number of copper-zinc compounds— Cu_2Zn , CuZn , CuZn_2 , CuZn_4 . J. Traube studied the capillary angle. T. Turner and M. T. Murray, and D. Meneghini showed that the hardness of annealed copper-zinc alloys gives a maximum when 33 to 34 per cent. of copper is present; the **tensile strength** was measured by G. Charpy, P. Ludwik, E. S. Shepherd, W. C. Roberts-Austen, M. Hanszel, W. C. Unwin, F. Dörinckel and J. Trockels, G. D. Bengough and O. F. Hudson, H. M. Brayton, L. Guillet, A. le Chatelier, E. S. Sperry, G. A. Dick, A. E. Tucker, O. Smalley, etc.; the **ductility**, by A. Guettier, C. J. B. Karsten, C. Karmarsch, E. Maey, W. C. Roberts-Austen, L. Guillet, G. Charpy, H. Behrens, A. Portevin, C. Barus, H. Tomlinson, etc.; and the **elastic limit**, by G. Charpy, H. Behrens, E. S. Sperry, etc. F. Dörinckel and J. Trockels studied the **impact test**. According to L. H. Adams, E. D. Williamson, and J. Johnston, the **compressibility** of brass (61.76Cu, 35.92Zn, 2.26Pb, 0.05Fe) is 0.89×10^{-6} per megabar, and for the change in vol. δv per c.c. between press. p_0 and p , they found $\delta v = 0.5 \times 10^{-4} + 0.875 \times 10^{-6}(p - p_0)$. E. Madelung and R. Fuchs gave 0.90×10^{-6} megabars per sq. cm. S. Lussana, W. Owens, and F. Dörinckel and J. Trockels measured the compressive strength of brasses. E. H. Amagat gave 0.00000953 for the coeff. of cubical compressibility; and 0.3275 for **Poisson's ratio**; and he gave 10,851 kgrms. per sq. mm. for the **modulus of elasticity**; W. Voigt gave 9220 kgrms. per sq. mm. The elastic modulus has also been measured by E. Weston, A. Gray, V. J. Blyth, and J. S. Dunlop, F. C. Lea and co-workers, G. Wertheim, G. Searle, N. Katzenelsohn, M. Baumeister, etc. F. Kohlrausch and E. H. Loomis found that the modulus of elasticity falls with a rise of temp. such that $E = E_0(1 - 0.000485\theta - 0.0000136\theta^2)$; and A. Gray, V. J. Blyth, and J. S. Dunlop found the **viscosity** increased with a rise of temp. K. Honda and S. Konno gave 1.55×10^8 at 20° for the coeff. of normal viscosity of rolled 59:39 brass at 20° .

R. Stribeck found the **brittleness** rises from 0·03 to 0·10 per cent. when the temp. rises from 300° to 500°. R. H. Thurston, and E. Grüneisen measured the **torsion modulus**. A. Masson, A. Kundt, and G. Wertheim have measured the **velocity of sound** in brass. The effects of annealing, cold work, etc., on the properties have been studied by F. Körber and P. J. H. Wieland, A. E. White, etc.

The **melting point** of copper was found by J. F. Daniell¹⁸ to decrease with the addition of increasing proportions of zinc—*vide* Fig. 66. G. Charpy gave :

Per cent. .	100	90·5	80·3	69·5	60·2	51·0	39·7	31·0	25·1	20·4	0
M.p. .	1054°	1020°	1000°	945°	880°	852°	812°	790°	700°	592°	415°

C. Féry found that when brass with 37 per cent. of zinc is heated in the electric furnace, at 1100°, the zinc is fractionally distilled. H. Moissan and A. J. P. O'Farrelley also studied the fractional distillation of zinc from the zinc-copper alloys. F. Braun observed the **volatilization** of zinc when a brass wire is heated by an electric discharge ; and W. Crookes, the volatilization of zinc from a cathode in a vacuum tube. L. Guillet and M. Ballay studied the **vapour pressure** of the zinc in these alloys, and found Raoult's law is not applicable. The **coefficient of thermal expansion** was measured by A. L. Lavoisier and P. S. de Laplace. P. Hidnet, W. Roy, A. Matthiessen, G. R. Dahlander, etc. H. Fizeau found 0·00001859 between 0° and 40°; H. le Chatelier, 0·0000225 at 707°; and F. Henning, for a brass with 7·5Cu, 27·7Zn, 0·3Sn, 0·5Pb, an expansion of 0·001879 between 0° and 100°. R. S. Willows found the **thermal conductivity** of brass to be about three times as great as for copper. L. Lorenz, T. Turner and D. M. Levy, A. Berget, G. Glage, F. Weber, N. Eumorfopoulos, F. E. Neumann, etc., have measured the thermal conductivity of brass. G. Wiedemann found the relative conductivity to be :

Cu : Zn .	100·0	8 : 1	6·5 : 1	4·7 : 1	1 : 1	0 : 100
Rel. cond. .	73·6	27·3	29·9	31·1	25·8	28·1

At 18°, C. H. Lees found a conductivity of 0·260 ; at 0°, 0·254 ; at -80°, 0·223 ; and at -160°, 0·181. F. Weber gave 0·791 for the **specific heat** of brass. F. Dörinckel and M. Werner obtained the results indicated in Table VIII ; there is a

TABLE VIII.—THE SPECIFIC HEAT OF ZINC-COPPER ALLOYS.

Cu per cent.	Temperature.

break near 460°, increasing in magnitude as the proportion of zinc increases. R. Schenck measured the ratio of the thermal and electrical conductivities. T. J. Baker could detect no heat change in the formation of brass with 0 to 30 per cent. of copper ; between 30 and 60 per cent. of copper, the **heat of formation** gradually rises to 46 Cals. per gram of alloy ; and gradually falls with increasing proportions of copper. A maximum in the curve corresponds with the compound Zn_2Cu , and a second smaller maximum with CuZn ; A. Galt also found a maximum corresponding with Cu_2Zn_3 . M. Herschkowitsch showed that the errors of experiment are large in comparison with the smallness of the magnitude being measured ;

and J. H. Gladstone discussed the effects of variations in the nature of the products of the reaction on the result.

B. Walter¹⁹ studied the **spark spectrum** given by the discharge between brass electrodes. R. Emden found the emission of light from brass begins at 405°. H. Rubens and R. Hagen studied the effect of temp. on the **emission of light**. The absorption and radiating power of brass for Hertz's waves was studied by J. R. von Geitler; while H. Knoblauch studied the **polarization angle** and the abnormal **dispersion** of brass for heat rays. W. G. Hankel found that an illuminated brass plate in water is first electropositive and then electronegative. W. Hallwachs found a brass plate is **photoelectric**, for when illuminated by the arc-light it becomes electrically positive. R. Hamer found the limiting frequency for the photoelectric effect to be $\lambda=3426 \pm 75$. B. Sabat found that the electrical conductivity of brass is raised by exposure to the radiations from **radium rays**. J. J. Thomson found that no radioactivity is induced by radium rays. E. Salles measured the diffusion coefficient for ionized gases. The ionization of air was found by J. Borgman to be stronger with brass than with copper.

J. Kinsky²⁰ could detect no transport of either metal relative to the other when an electric current is passed through brass. J. Haas measured the specific **electrical conductivity** in rec. ohms, and the specific **electrical resistance** in ohms, of zinc-copper alloys at 0°, and found:

Zn per cent.	0	0.71	5.51	20.29	34.23	46.85	99.53
Sp. resist.	0.01584	0.01833	0.03010	0.05064	0.06302	0.04314	0.05883
Temp. coeff.	0.004322	0.003725	0.002383	0.001639	0.001579	0.003105	0.0038
Sp. conduct.	63.13	54.56	33.22	19.75	15.87	23.18	17.00

The curve for the sp. resistance rises rapidly until 5 per cent. of zinc is present, and it then rises more slowly until 34 per cent. of zinc is present, when it falls rapidly until 47 per cent. of zinc is present. The temp. coeff. falls rapidly until 5 per cent. of zinc is present, and afterwards more gradually; the fall is nearly constant with between 17 and 30 per cent. of copper; and it then steadily rises until 47 per cent. is present. E. F. Northrup measured the resistance of solid and molten brass; and R. Schenck, the ratio of the thermal and electrical conductivities.

According to A. Matthiessen and C. Vogt, the conductivity of alloys of hard-drawn wires between 0° and 100°, when the conductivity of silver is 100 units, is $60.376-0.14916\theta+0.0002473\theta^2$ for alloys with 5.03 per cent. of zinc; $46.934-0.095947\theta+0.0001423\theta^2$ for alloys with 10.88 per cent. of zinc; $21.298-0.040029\theta+0.00003832\theta^2$ for alloys with 23.61 per cent. of zinc; $21.708-0.027632\theta+0.00002698\theta^2$ for alloys with 29.45 per cent. of zinc; and $21.793-0.029939\theta+0.00002916\theta^2$ for alloys with 42.05 per cent. of zinc. Other observations on the electrical conductivity of copper-zinc alloys were made by W. H. Mordy, G. Charpy, R. H. Weber, F. Weber, F. E. Neumann, G. Wiedemann, A. Oberbeck and J. Bergmann, H. le Chatelier, A. Berget, L. Lorenz, R. Benoit, O. D. Chwolson, H. Tomlinson, N. A. Puschin and W. Rjaschsky, L. Norsa, W. Fränkel, and H. Becker, etc. R. S. Willows observed no difference in the conductivity of brass for continuous and alternating currents at the temp. of liquid air, of liquid carbon dioxide, at 20°, and at 100°. According to D. Goldhammer, the resistance of brass in a magnetic field was not appreciably changed. W. Guertler argued that the minimum in the electrical conductivity curve corresponding with Cu_2Zn cannot be accepted as evidence of the existence of a compound, but a maximum in the curve indicates the presence of a compound of unknown composition; J. Haas found a maximum in the sp. resistance curve and a minimum in the temp. coeff. corresponding with Cu_2Zn ; A. Matthiessen and C. Vogt's, and R. H. Weber's observations also lead to the assumption that compounds are present; C. Liebenoff's observations indicated the formation of CuZn ; and H. le Chatelier's of CuZn_2 . E. Bornemann and K. Wagenmann obtained a minimum in the electrical conductivity curve of the molten metal corresponding with Cu_2Zn_3 , showing that

this compound probably exists in the soln. A. Jaamaa and Y. E. G. Leinberg measured the resistance of powdered brass mixed with marble.

The **potential difference** of alloys of copper and zinc was measured by W. E. Ayrton and J. Perry²¹ towards water (-0.231 volt); dil. sulphuric acid, $1:5$ (-0.016 volt); conc. soln. ammonium chloride (-0.348 volt); aq. soln. sodium chloride, sp. gr. 1.18 at 20.5° (-0.435 volt); and a conc. soln. of alum (-0.014 volt). The potential towards cyanide soln. was investigated by F. Spitzer. W. D. Bancroft, J. L. R. Morgan, J. Trowbridge and E. K. Stevens, C. Liebenoff, and H. E. Armstrong, measured the **electromotive force** against platinum in water, and in dil. sulphuric acid; E. Branley, the e.m.f. against copper in dil. sulphuric acid; M. Herschkowitsch, F. Haber, and W. Reinders, the e.m.f. against amalgamated zinc in a soln. of zinc sulphate; S. P. Thompson, against carbon in a soln. of potassium cyanide; H. Pellat, against gold; W. E. Ayrton and J. Perry, against carbon, zinc, tin, lead, iron, and platinum. N. A. Puschin found breaks in the e.m.f. curve of zinc-copper alloys in $N\text{-ZnSO}_4$ corresponding with the compounds Cu_2Zn , CuZn , CuZn_2 , and CuZn_3 . A. P. Laurie, and M. Herschkowitsch also inferred the existence of definite compounds— Cu_2Zn , etc., from the breaks in the e.m.f. curves. F. Sauerwald measured the e.m.f. of copper-zinc alloys against soln. of zinc chloride. G. Tammann studied the difference in the potentials of alloys prepared by electrodeposition and by fusion. P. W. Bridgman measured the **thermoelectromotive force**, or the Seebeck effect, of brass wires, one in the normal state and the other under a tension of 2800 kgrms. per sq. cm. At 52° , $E = (0.00022T - 0.073T^2) \times 10^{-6}$ volts; at 77° , $E = (0.00013T - 0.0712T^2) \times 10^{-6}$ volts; and at 94° , $E = (0.00047T - 0.075T^2) \times 10^{-6}$ volts. E. Sedström measured the **Peltier effect** with copper-zinc alloys. R. H. Weber studied the **magnetic susceptibility** of the brasses and found a maximum -5.3×10^{-6} with the composition CuZn_2 , the compositions Cu_2Zn and CuZn are not clearly marked on the curve, but there are changes in the direction of the curve at approximately Cu_2Zn_3 and CuZn_3 . L. H. Manhall and R. L. Sanford discussed the magnetic susceptibility of ferruginous brasses.

T. G. Bamford and W. E. Ballard²² have discussed the action of different gases on brass. When brass is heated in **air**, it acquires a series of colours from surface oxidation. L. Löwenherz showed that it becomes pale gold when heated to 281° for 15 mins., golden-yellow at 341° , and passes through a series of orange and pink colours changing to green. The coloration, said H. Schwarz, is due to the formation of a film of cuprous oxide which is removed by treatment with a conc. soln. of sodium chloride. H. Behrens found pre-treatment of the zinc-copper alloy with dil. sulphuric acid favours the production of the heat films. E. Jordis and W. Rosenhaupt found that at 220° brass with 90 per cent. copper is more rapidly attacked by moist than by dry **oxygen**, and there is a break in the curve which represents the relation between the rate of attack, and the composition which led to the inference that a compound Cu_3Zn is present in the alloy. G. Tammann and W. Köster studied the formation of films on brasses of different composition when warmed in air. F. Schulze-Berge found that brass acquires a negative charge when exposed to **ozone**, and coupled with brass in air; with **ammonia** or **hydrogen** the charge is positive. T. G. Bamford and W. E. Ballard found that hydrogen is absorbed in relatively large quantities by $70:30$ brass between 500° and 900° , and that most of this gas is retained on cooling. G. Guillemin and B. Delachanal observed the absorption of hydrogen, **methane**, **carbon monoxide**, and **carbon dioxide** by brass. R. B. Warder reported that when brass is heated to redness in a stream of hydrogen for several hours, the rate of loss of weight diminishes much more rapidly than corresponds with the whole quantity of zinc present. A. Bobierre, and A. K. Haslam made observations on the action of hydrogen on heated brass; and A. Ledebur reported that when brass containing sulphur is heated in a stream of hydrogen, no hydrogen sulphide is formed, showing that the sulphur is probably combined with the zinc and not with the copper or tin.

J. Pintsch noted that brass is more resistant than copper towards the exhaust gases of gas engines. U. Kreusler observed that brass is not attacked by dry **chlorine**, but is attacked by the moist gas. M. Herschkowitsch found an aq. soln. of **bromine** attacks brass.

T. Ihmori estimated that 0.27×10^{-6} grm. of **water** per sq. cm. condenses on a clear surface of brass. A. Wagner found that in the absence of carbon dioxide water is without action on brass, or at the most the action is very feeble. J. H. Aber-son found that water dissolves much zinc from brass—zinc oxide is first formed, and this is dissolved by the absorbed carbon dioxide, and he added that filters for soft water should be constructed without brass. X. Rocques observed that water in the presence of oxygen, and of compounds of nitrogen or ammonium salts, attacks brass more strongly than copper.

A. T. Lincoln and co-workers, F. Sauerwald, J. H. Reedy and B. Feuer, S. D. Whyte and C. H. Desch, H. W. Brounson, P. Davidson, A. S. Cushman, A. A. Bado and R. A. Trelles, R. B. Abrams, and P. E. Howe have studied the corrosion by **salt solutions** of copper-zinc alloys and of some complex brasses when used as anode in soln. of electrolytes, as well as the chemical corrosion of these metals. The metals were annealed at 400° . In general, the composition of the corrosion product with alloys with 50 per cent. of copper upwards is the same as that of the test-piece, but with lower proportions of copper, the corrosion product is virtually zinc. Otherwise expressed, the α , $\alpha+\beta$, and the β -brasses yield corrosion products with the same composition as the brass; the

FIG. 67.—Electrolytic Corrosion of Copper-Zinc Alloys by Solutions of Sodium Chloride.

presence of γ -crystals causes a marked decrease in the amount of corrosion; while the $\gamma+\epsilon$ and $\epsilon+\eta$ brasses yield a corrosion product of zinc. The results with the tin-brasses were virtually the same as with zinc-brasses. The results with a N-soln. of **sodium chloride** are indicated in Fig. 67; the boundaries of the different solid soln. are indicated by dotted lines; the upper curve shows the variations in the amount of corrosion, and the lower curve represents grams of copper in the corrosion product. The curve for the γ -field is interpolated.

A. T. Lincoln, and G. C. Bartells found that the corrosion with synthetic **sea-water** is practically the same as with aq. soln. of sodium chloride. W. A. Tilden found that brass may be boiled with a soln. of sodium chloride for any length of time, without alteration, provided air is entirely excluded, and the attack by sea-water on ship's sheathing is generally worse near the water-line. M. Berthelot stated that with dil. soln. of alkali chlorides exposed to air, cuprous oxide and atacamite are formed, and zinc dissolved. The reports of the action of sea-water are not always concordant. A. Bobierre found that the zinc appears to be dissolved, and an oxidation product of copper formed. W. A. Tilden found that brass with 60 per cent. of copper is less attacked by sea-water and soln. of chlorides than is copper; corrosion pits are produced with brass in contact with other metals. Other observations were made by O. Silberrad, L. Belladen, R. Finkener, H. S. Rawdon, F. C. Calvert and R. Johnson, M. Diegel, etc. According to the last-named, the destructive action of sea-water on copper alloys rich in zinc is traceable to the destruction of the alloy by the extraction of zinc. When two metals are in contact in sea-water a voltaic current is set up, the metal being especially attacked which stands highest in the electromotive series—in the case of copper alloys, therefore

those richest in zinc. As a rule, the greater the difference in the electromotive order between the alloy and the metal in contact with it, the greater is the corrosion. According to P. de Wurstemberger, the mode in which brass is dezincified in contact with sea-water varies according to whether the brass contains only one phase, whether all α or all β , or both. In the first case the metal becomes gradually more or less uniformly coated with spongy copper, in the second case the β constituent is attacked first, and the metal has the appearance of a network of channels surrounding the α -grains. The primary cause of dezincification appears to be the deposition of a film of metallic copper on the surface of the metal from a salt or oxide of copper formed by the action of the salt water on the brass, and this gives rise to a concentration of copper ions sufficient to hinder polarization, the zinc then dissolves by electrolytic action. Selective corrosion is due to electrolytic action of stray or local currents, whereas dezincification may be considered to be due to selective corrosion that is still going on or has already stopped. The former phenomenon is characterized by the appearance of gelatinous deposits of an oxychloride of zinc along the α -crystal boundaries, and the water in contact with the metal reacts alkaline, whereas the latter is accompanied by deposition of spongy copper. O. Lasche discussed corrosion due to stray currents and local corrosion. R. B. Abrams studied the dezincification of brass.

W. A. Tilden found sodium chloride soln. attack brass faster than those of **magnesium chloride**. A. Wagner found that in the presence of air free from carbon dioxide, brass with 65 per cent. of copper, is but little attacked by soln. of magnesium or **potassium chloride**, with **ammonium chloride** there is strong corrosion; with air containing carbon dioxide, the action of ammonium chloride is reduced about one-half, and that with magnesium and potassium chloride soln. is augmented about 21 times. T. J. Baker noted that brass dissolves rapidly, with the development of gas, in a mixed soln. of **ferric and ammonium chlorides**; and in one of **cupric and ammonium chlorides**. According to H. P. Pearson, an alkaline soln. of **sodium hypochlorite** attacks copper-zinc alloys, slowly forming a dull green deposit, but no trace of either metal passes into soln.

According to T. G. Bamford and W. E. Ballard, brass at 300° absorbs **sulphur dioxide**, and the gas is eliminated from the metal between 950° and 1050° under reduced press. A. Wagner found that an alloy with 64.5 per cent. copper is not appreciably attacked by a soln. of **potassium sulphate** exposed to air free from carbon dioxide. A. T. Lincoln, D. Klein, and P. E. Howe observed the anodic corrosion of zinc-copper alloys by a *N*-soln. of **sodium sulphate**. The amount of corrosion is practically the same with all the alloys. N. A. Puschin found alloys with 0 to 14 at. per cent. of copper are feebly attacked by *N*-soln. of **zinc sulphate** at ordinary temp. J. Girard observed that 10 per cent. soln. of **sodium thiosulphate** attack brass a little, at 60°–65°. A. T. Lincoln, D. Klein, and P. E. Howe measured the action of *N*-soln. of **sodium persulphate** in alkaline soln. The alloys with 73.4 to 93.6 per cent. of copper were badly corroded on the test-pieces exposed to air; the 22.6 per cent. copper alloy was coated with a layer of copper owing to the removal of the zinc; the 3.1 to 10.5 per cent. copper alloy was coated with a black deposit; while the 60.3 to 76.3 per cent. copper alloy remained practically unchanged. With aq. soln. of sodium persulphate, the brasses of high copper content were badly corroded, the alloys with 51.3 to 3.1 per cent. of copper were coated with a film of copper. A. Wagner found that in the presence of air, and the absence of carbon dioxide, a soln. of **potassium nitrate** exerts no action on brass with 65 per cent. of copper; but if carbon dioxide be present there is a slight action. A. T. Lincoln, D. Klein, and P. E. Howe studied the action of a *N*-soln. of **sodium nitrate** and of **ammonium nitrate** on an anode of zinc-copper alloys. The corrosion products contained varying proportions of zinc and cupric hydroxides. With sodium nitrate, there is a gradual increase in corrosion as the amount of copper decreases until the $\beta + \gamma$ area is reached, while in the $\gamma + \epsilon$ area the alloy is less corroded, and as the proportion of copper decreases, the amount of corrosion increases in a marked

degree. Similar results were obtained with soln. of ammonium nitrate. A. Wagner found that a soln. of **sodium carbonate** does not attack brass when exposed to air free from carbon dioxide; and the attack by a soln. of **potassium carbonate** in the presence of air with carbon dioxide is feeble. A. T. Lincoln, D. Klein, and P. E. Howe found that the anodic corrosion of copper-zinc alloys by *N*-soln. of sodium carbonate is feeble—white adherent coatings were formed on alloys with 3.1 to 10.5 per cent. of copper; the alloys with 47.6–51.3 per cent. of copper were covered with a green film, and those with more copper were slightly discoloured. They also studied the anodic corrosion of zinc-copper alloys in *N*-soln. of **ammonium oxalate**; those alloys with less than 47.6 per cent. of copper developed insulating films; with the other alloys, the amount of corrosion increased with decreasing content of copper, making a maximum in brasses with $\alpha + \beta$ -crystals, and then decreasing rapidly with the appearance of the γ -crystals. In the anodic corrosion in *N*-soln. of **sodium acetate**, the amount of corrosion increases rapidly with decreasing copper content, attains a maximum in the $\alpha + \beta$ -region, and diminishes with the appearance of the γ -crystals. W. H. Walenn noted the solvent action of a soln. of **potassium cyanide** mixed with ammonium tartrate, and J. J. Hesz of a mixed soln. of potassium cyanide, sodium hydrocarbonate, and ammonium chloride.

According to C. J. B. Karsten, alloys with over 50 per cent. of copper exhibit the reactions of copper towards **acids**, but alloys with less than 50 per cent. of copper dissolve completely in acids which have scarcely any action on copper alone, and this the more rapidly, the greater the proportion of zinc. If the quantity of acid be not sufficient to dissolve the whole of the alloy, copper is reprecipitated until all the zinc is dissolved. J. J. Berzelius noted that brass becomes red when rubbed with hydrochloric acid, because the zinc dissolves in preference to the copper. O. Sackur, P. Maus, and A. Siemens found that there are breaks in the acid solubility curve of alloys with about 45 and 62 per cent. of copper; alloys with less than 45 per cent. of copper do not yield copper to $\frac{1}{20}$ *N*-sulphuric acid, but those with over 62 per cent. of copper yield copper as well as zinc to the dil. acid. H. Behrens found that the annealed alloy dissolves more readily in acid and salt soln. than the cast alloy. F. C. Calvert and R. Johnson found that sulphuric acid, at 150°, dissolves only zinc from alloys with an excess of zinc, and both copper and zinc are dissolved from alloys with an excess of copper; $\text{H}_2\text{SO}_4 \cdot 2\text{H}_2\text{O}$, at 150°, acts feebly on copper-zinc alloys, and not at all on that corresponding with CuZn ; A. Matthiessen, J. Laubheimer, H. Behrens, and O. Haug have also made observations on this subject. R. C. Griffin found the solvent action of sulphuric acid is lessened by formaldehyde. E. Harbeck found that a brass anode is not attacked by sulphuric acid of sp. gr. 1.53. F. C. Calvert and R. Johnson found **nitric acid**, sp. gr. 1.14, dissolves approximately equi-atomic proportions of the two metals from CuZn , and an acid of sp. gr. 1.08 approximately 5 atomic proportions of zinc for one of copper. Nitric acid of sp. gr. 1.1 acts but little on alloys with an excess of copper, and readily on alloys with an excess of zinc. R. C. Griffin found that formaldehyde slows down the attack with nitric acid. B. C. Banerji and N. R. Dhar found the presence of ferric chloride or nitrate, or ferrous sulphate accelerates the action of nitric acid on brass, while the presence of manganese sulphate, potassium chlorate, or potassium permanganate retards the action. F. C. Calvert and R. Johnson found that conc. **hydrochloric acid** dissolves zinc completely from the alloy with equi-atomic proportions of the two metals; an acid of sp. gr. 1.05 does not act on this alloy or on alloys richer in copper, but it removes the zinc from alloys with a smaller proportion of copper, and this the more rapidly the greater the proportion of zinc. T. Schwarz found that **acetic acid** and **lactic acid** dissolve copper from brass; A. Gawlowsky, that 4 per cent. acetic acid readily attacks brass; and E. J. Paessler, that **fatty acids** attack brass.

J. J. Berzelius noted that brass becomes white if rubbed with aq. **ammonia** owing to the dissolution of the copper and not the zinc. J. Y. McLellan reported that if a piece of brass or brass turnings be covered with aq. ammonia, sp. gr. 0.880,

and confined in a stoppered bottle, a violet soln. will be produced in a few days owing to the dissolution of copper from the brass. H. Behrens found the attack of aq. ammonia is greatest on alloys with a moderate proportion of copper. W. Venator found a soln. of **sodium hydroxide** attacks brass slightly dissolving only the zinc; while G. Charpy found that a soln. of **potassium hydroxide** rapidly attacks copper-zinc alloys rich in zinc, and dissolves only the zinc, while alloys with about 25 per cent. of copper are attacked more slowly, because, he said, of the presence of Zn_4Cu . H. Behrens found that if the alkali lye contains some cupric tartrate, it attacks these alloys more strongly than does aq. ammonia. A. Wagner found a soln. of **calcium hydroxide** behaves like sodium hydroxide towards brass. J. J. Redwood found that the percentage loss when brass is treated with **mineral oil** is 0.2455; with **tallow oil**, 0.04929; with **lard oil**, 0.08860; with **sperm oil**, 0.02743; with **whale oil**, 0.02547; and with **seal oil**, 0.00951. A bright green coloration was produced with **olive oil**. A. Gawlowsky found that **rape seed oil** attacks brass strongly, raw **petroleum** very little, and **wort** not at all.

C. J. B. Karsten showed that alloys of zinc with over 50 per cent. of copper do not precipitate copper from soln. of its salts, but if less than this proportion of copper is present, the alloy decomposes the cupric salt at the expense of the contained zinc. O. Sackur, P. Maus, and A. Siemens found that alloys with 0 to 41 per cent. of copper precipitate copper from soln. of its salts; alloys with 45 to 60 per cent. of copper do not precipitate that element from soln. of cupric cyanide or thiocyanate; and alloys with over 62 per cent. of copper do not precipitate copper from ammoniacal soln. of the halides. The curve showing the activity of the copper-zinc alloys in this connection has breaks with 41–45 and 60–62 per cent. of copper. M. Herschkowitsch and H. Behrens, and G. Tammann have made observations on this subject.

A. F. Gehlen²³ noted that silver and zinc readily unite when fused in the respective proportions 1 : 2, forming a fine-grained malleable alloy with a tinge less blue than that of zinc. C. R. A. Wright showed that the two metals are miscible in all proportions when in the fluid state. N. W. Fischer also observed that an alloy of the two elements is obtained when a soln. of silver nitrate is precipitated with zinc. F. Mylius and O. Fromm made a similar observation. According to N. A. Puschin and M. Maksimenko, silver dissolves in small quantities in solid zinc, and silver dissolves up to 30 at. per cent. of zinc. The f.p. curve has been studied by H. Gautier, G. J. Petrenko, C. T. Heycock and F. H. Neville, H. C. H. Carpenter. According to G. J. Petrenko, there is a maximum at 710° corresponding with **silver zincide**, Ag_3Zn_2 ; the compound AgZn appears to be formed at 690° ; Ag_2Zn_3 , at 670° ; and Ag_2Zn_5 , at 636° ; but there are differences of opinion as to the compounds which are formed; N. A. Puschin and M. Maksimenko give AgZn , Ag_2Zn_3 , AgZn_4 , and AgZn_6 . G. J. Petrenko assumed that when the mixed crystals of ZnAg and Ag_3Zn_2 are slowly cooled, they break up into mixed crystals with 21.7 per cent. of zinc, and $\beta\text{-ZnAg}$; the latter at 266° develops heat and forms crystals of $\alpha\text{-ZnAg}$. H. C. H. Carpenter and W. Whiteley's analysis of the system is shown in Fig. 68, and it shows that with 0 to 60 at. per cent., the diagram closely resembles that of the copper-zinc system for the same conc. There are six phases: (i) α -phase is stable at ordinary temp., and ranges between 100 and 62.7 at. per cent. of silver; (ii) β -phase exists only above 264° , for on cooling there is a eutectoidal inversion to $\alpha + \gamma$; (iii) γ -phase between 40 and 37.3 at. per cent. of silver, and is stable at ordinary temp.—with 40 at. per cent., this is silver zincide Ag_2Zn_3 ; (iv) δ -phase, with between 29 and 14.3 at. per cent. of silver, is stable at ordinary temp.; (v) ϵ -phase exists only above 300° approximately; and (vi) η -phase, with between 0 and 1 at. per cent. of silver, is stable at ordinary temp. There is some indecisive evidence of the existence of a compound Ag_2Zn_5 . K. Bornemann found the compound Ag_2Zn_5 can exist at ordinary temp., and R. Kremann and F. Hofmeier say that it is the colour of nickel.

According to N. A. Puschin, the colour of alloys with from 0 to 30 at. per cent. of silver is indistinguishable from that of zinc, and they have a well-defined crystalline structure and coarse-grained fracture; alloys with 39 at. per cent. of silver

FIG. 68.—Fusion Curves of Zinc-Silver Alloys.

FIG. 69.—Fusion Curve of Zinc-Gold Alloys.

are white with a conchoidal fracture; alloys with 50 at. per cent. of silver are rose-coloured; and those with 63 per cent. of silver are pale yellow. C. T. Heycock and F. H. Neville, G. J. Petrenko, G. Charpy, H. C. H. Carpenter, and others have studied the minute structure of the alloys. E. Maey found a break in the sp. gr. curve for 80 at. per cent. of zinc. G. J. Petrenko found a maximum in the hardness curve between 47.61 and 60 per cent. of zinc; and N. A. Puschin obtained a maximum hardness with 33 and a second maximum with 50 at. per cent. of silver. C. T. Heycock and F. H. Neville, and E. M. Pélégot studied the tensile strength of these alloys; and E. C. Bain, the X-radiograms; C. Barus and V. Strouhal measured the electrical conductivity; N. A. Puschin, the electrical resistance, the electrical conductivity, the temp. coeff. of the resistance, and the thermal e.m.f. M. Herschkowitsch found a break in the potential curve of alloys against zinc in $N\text{-ZnSO}_4$ soln. with alloys containing 80 at. per cent. of zinc corresponding with AgZn_2 . R. Kremann and F. Hofmeier measured the e.m.f. of the cell $\text{Zn} | N\text{-ZnSO}_4 | \text{Ag-Zn alloy}$. E. M. Pélégot studied the action of hydrogen sulphide and alkali sulphides on these alloys; and C. Montemartini and E. Colonna, the formation of ammonia when these alloys are dissolved in nitric acid. C. R. Groves and T. Turner observed that zinc is volatilized when these alloys are heated in vacuo below 1000° , and some silver also if over 1000° . D. Palitsch said that an alloy with 7 to 10 per cent. of silver dissolves in hydrochloric acid, forming a residue of allotropic silver. E. Sedström measured the Peltier effect with zinc-silver alloys. G. Tammann studied the difference in the potentials of alloys prepared by electrodeposition and by fusion.

Alloys of gold and zinc were early prepared by A. F. Gehlen,²⁴ J. Hellot, and C. Hatchett. The f.p. curve has been studied by C. T. Heycock and F. H. Neville, N. A. Puschin, C. H. Desch, and R. Vogel. The results are shown in Fig. 69. R. Vogel interprets the diagram by assuming that the **gold zincide**, AuZn , is represented by a maximum on the f.p. curve at 744° , and Au_3Zn_5 appears to be formed at 651° , and AuZn_3 at 490° . There is a eutectic at 648° . The colour of the gold zinc alloys changes from a pale yellow to a fine reddish-lilac tint as the proportion of zinc changes from 14 to 25 per cent.; with further additions of zinc, the colour gradually fades, and alloys with 25 to 30 per cent. of zinc consist of a white matrix with lilac-coloured polygonal crystals of AuZn . E. Matthey studied the homogeneity of the alloys. The microstructure was investigated by R. Vogel, and W. C. Roberts-Austen and F. Osmond; the sp. gr., by C. Hatchett; the hardness, by R. Vogel; the tensile strength, by W. C. Roberts-Austen; and the e.m.f. of

the cell $\text{Zn} \mid \frac{1}{N}\text{-ZnSO}_4 \mid \text{Au-Zn alloy}$, by N. A. Puschin, who inferred the existence of the compounds AuZn_6 , AuZn_2 , and AuZn . C. R. Groves and T. Turner found that if the alloys with a low proportion of gold be heated 30–90 mins. in vacuo at 500° , the composition of the residue corresponds approximately with AuZn ; if zinc cuttings be heated with sodium hydroxide in a gold crucible to 420° , the crucible is spoilt. E. Sedström measured the Peltier effect with gold-zinc alloys. G. Tammann studied the chemical activity of the alloy.

F. Stromeyer²⁵ prepared an alloy of cadmium and copper by melting the two elements together; C. R. A. Wright found that when melted, the two elements are miscible in all proportions; and P. Denso found that copper dissolves immediately in melted cadmium. F. M. Raoult found an alloy is produced when copper foil in contact with a piece of cadmium wire is dipped in a conc. soln. of cadmium sulphate. J. B. Senderens obtained an alloy by placing soln. of cupric sulphate, chloride, or acetate in a cadmium vessel. The f.p. curve of the two elements has been studied by R. Sahmen, C. T. Heycock and F. H. Neville, G. D. Roos, and H. le Chatelier. The results of the first-named are illustrated by Fig. 70. There are two eutectics corresponding respectively with 59.5 per cent. of cadmium at 542° , and with 98.84 per cent. of cadmium at 314° . The maximum corresponds with cupric

FIG. 70.—Fusion Curve of Copper-Cadmium Alloys.

FIG. 71.—Fusion Curve of Silver-Cadmium Alloys.

FIG. 72.—Fusion Curve of Gold-Cadmium Alloys.

cadmide, Cu_2Cd_3 , melting at 564° , and with a heat of formation, according to W. D. Roos, of 47.7 ± 5.2 Cals. per mol, and a heat of fusion of 26.05 Cals. per mol. There is an abrupt change in the direction of the curve between 552° and 542° , with mixtures with between 56.5 and 59.5 per cent. of cadmium, and the solid alloys contain needle-like crystals of the cupride Cu_2Cd . F. Mylius and O. Fromm remarked on the greater sp. gr. of the compound Cu_2Cd than that of the separate constituents, and added that hydrogen is evolved by conc. hydrochloric acid, the copper is dissolved, forming cuprous chloride. P. Denso described the cupride CuCd_3 formed by crystallization from alloys with 1 to 10 per cent. of copper. The m.p. is above the vaporization temp. of cadmium. The faculty of copper to form solid soln. with cadmium, said N. A. Puschin, is feebler than with zinc. According to N. A. Puschin, alloys with less than 60 at. per cent. of copper are whitish, those with 68 per cent. are pale yellow, those with 75 per cent. are yellow, 80 per cent. rose, and 90 per cent. copper-red. R. Sahmen described the fracture; P. Denso, and R. Sahmen, the minute structure; G. Tammann and K. Dahl, the gliding planes at diff. temp.; W. Biltz and C. Haase, and E. Maey, the sp. gr., that of Cu_2Cd_3 being 9.35 at $25^\circ/4^\circ$; W. Biltz and C. Haase, the heat of formation, viz., -1.3 Cals.; N. A. Puschin, the hardness; and L. Guillet, G. Chaudoir, and F. Stromeyer, the tensile strength. W. C. Smith studied the mechanical and electrical properties of these alloys. E. Bornemann and K. Wagenmann found the electrical conductivity curve of the liquid alloys has a minimum corresponding with Cu_2Cd_3 , making it possible that this cupride exists in the molten metal. G. Tammann studied the difference in the potentials of cadmium-copper alloys prepared by electrodeposition, and by fusion.

B. Wood²⁶ prepared a malleable, hard, and tough alloy of silver and cadmium

in the proportions 2 : 1, and found that the alloy 1 : 2 was brittle. J. B. Senderens made an alloy corresponding with AgCd_3 , and F. Mylius and O. Fromm observed that an alloy of the two metals is formed by the action of cadmium on a soln. of silver nitrate. C. R. A. Wright found that the molten metals are mutually soluble in all proportions. According to C. T. Heycock and F. H. Neville, the m.p. of cadmium is raised, not lowered, by the addition of silver. T. K. Rose explained the complex f.p. diagram by assuming that the following **cadmium argentides**, AgCd_3 , Ag_2Cd_3 , AgCd , Ag_3Cd_2 , Ag_2Cd , and Ag_3Cd , are formed, and G. Bruni and E. Quercigh assumed the existence of AgCd and AgCd_4 . T. K. Rose commented on the analogy between Ag_2Cd_3 and Ag_2Zn_3 , and between AgCd and AgZn . It is also stated that the two latter undergo allotropic changes below their m.p. E. Maey got a break in the sp. gr. curve corresponding with AgCd_3 . The f.p. curve has been studied by H. Gautier, T. K. Rose, G. Bruni and E. Quercigh, and G. J. Petrenko and E. S. Federoff. A summary of the results is indicated in Fig. 71. H. C. H. Carpenter emphasized the close relationships between the copper-zinc, silver-zinc, and such portions of the silver-cadmium equilibrium diagram as are known; and he suggests that in each system it is the compound X_2Y_3 —where X represents Cu or Ag, and Y, Zn or Cd—which determines the character of the α - and β -phases, between 0 and 60 at. per cent. of zinc or cadmium. Otherwise, there is no eutectic in the silver-cadmium diagram, and solid soln. are formed throughout the series. R. Kremann and H. Ruderer measured the e.m.f., and E. Sedström, the Peltier effect of silver-cadmium alloys. G. Tammann studied the potential of alloys prepared by electrodeposition and by fusion; and N. S. Kurnakoff and A. N. Achnasaroﬀ, the effect of the velocity of cooling on the hardness and microstructure. E. Schreiner and co-workers measured the e.m.f. of silver-cadmium alloys. E. C. Bain studied the X-radiograms.

C. T. Heycock and F. H. Neville²⁷ made alloys of gold and cadmium, and studied their fusion points. F. Mylius and O. Fromm made alloys of these two metals by the action of cadmium on a soln. of auric chloride. According to P. Saldau, solid gold can dissolve up to 30 at. per cent. of cadmium, but solid cadmium only up to 2 at. per cent. of gold. R. Vogel, and P. Saldau have constructed equilibrium diagrams, Fig. 72. There is evidence of the formation of **cadmium auride**, Au_4Cd_3 , at 625°; and of AuCd_3 at 495°, with a eutectic at 303° and 87 per cent.; and of AuCd_3 at 495°, with a eutectic at 303° and 87 per cent. of cadmium. A maximum in the curve corresponds with the compound AuCd . The two compounds AuCd and AuCd_3 are represented by cusps in the electrical conductivity curves. The hardness has been measured by P. Saldau, and by R. Vogel; there are maxima with 18 to 30 per cent. and 51 to 63 per cent. of cadmium. P. Saldau measured the e.m.f. of the cell $\text{Cd} \mid \text{N-CdSO}_4 \mid \text{Cd-Au}$ alloy. He also found that the compound Au_4Cd_3 marks the limit of solid soln. in unannealed specimens and is not a real compound. W. C. Roberts-Austen measured the tensile strength of the alloys, and W. C. Roberts-Austen and F. Osmond, and R. Vogel studied the minute structure. Gold or silver alloyed with either cadmium or zinc can be parted with nitric or sulphuric acid. E. Sedström measured the Peltier effect with gold-cadmium alloys. G. Tammann studied the chemical activity of the alloy.

Alloys of copper and calcium have been prepared by L. Hackspill²⁸ by reducing cupric chloride with calcium at a red heat in vacuo; and he stated that the two metals are mutually soluble in all proportions. The alloys are orange-yellow, brittle, and have a crystalline fracture; they oxidize readily in air, and decompose water. L. Donsky found that one per cent. of calcium depresses the m.p. of copper 8°, and 5 per cent. lowers it 74°. N. Baar found what seems to be a eutectic at about 910°; with 5.7 per cent. of calcium, and one at 560° with 38 per cent. of calcium. There is also evidence of the formation of one **calcium cupride**, Cu_4Ca , as shown by the f.p. curve, Fig. 73. A thermal change unaccompanied by a change of structure occurs at 480° in all alloys containing CaCu_4 ; these alloys are all white,

and unstable in air. Alloys with over one per cent. of calcium decompose cold water with the evolution of hydrogen. L. Hackspill prepared homogeneous alloys of silver and calcium by reducing silver chloride with calcium at a dull red heat in vacuo. The alloys are grey, and brittle, and have a crystalline fracture; they oxidize readily in air, and are decomposed by cold water. G. Tammann studied the chemical activity of the alloy. C. Vickers tried the effect of calcium, barium, and strontium as deoxidizers, etc., on copper.

N. Baar studied the f.p. curve of calcium and silver, and found evidence of the formation of the **calcium argentides**: Ag_4Ca , Ag_3Ca , Ag_2Ca , and AgCa_2 —the latter is more or less doubtful. The f.p. curves shown in Fig. 74, are somewhat

FIG. 73.—Fusion Curve of Copper-Calcium Alloys.

FIG. 74.—Fusion Curve of Silver-Calcium Alloys.

complex. The compounds Ag_3Ca_2 and AgCa being marked by maxima in the f.p. curve at 726° and 665° respectively, whilst the compounds Ag_4Ca , Ag_2Ca , and possibly AgCa_2 , are formed at 683° , 595° , and 555° respectively. Solid soln. containing AgCa and AgCa_2 undergo a transformation at a lower temp. All the alloys containing more than 11 per cent. Ca decompose water. G. Tammann studied the chemical activity of the alloys.

L. Donsky found the f.p. curve of calcium and magnesium alloys to be of the simple W-type, Fig. 75. One compound, **calcium magneside**, Ca_3Mg_4 , is formed with a maximum at 715° , and eutectics at 514° and 446° with respectively 18.7 and 78.7 per cent. of calcium. Solid soln. are not formed to any appreciable extent. The magneside Ca_3Mg_4 is brittle, and silvery in appearance; W. Biltz and G. Hohorst gave 1.701 for the sp. gr. at $25^\circ/4^\circ$; and 127.9 for the mol. vol. L. Donsky found that it is stable in air, and but slowly acted on by water. The alloys of zinc and calcium were studied by H. Caron, G. vom Rath, T. H. Norton and E. Twitchell, H. Moissan, and L. Donsky. F. von Kügelgen and E. O. Seward prepared them by the electrolysis of molten calcium chloride with a zinc cathode. W. Moldenhauer and J. Andersen made alloys of zinc and calcium by the electrolysis of a molten mixture of calcium chloride with 15 per cent. of potassium chloride in an iron crucible containing some molten zinc which served as cathode; a graphite rod was used as anode. L. Donsky found that the f.p. curve of alloys of zinc and calcium has two maxima, Fig. 76, at 717° and 5.7 per cent. calcium and 688° and 28 per cent. of calcium, corresponding with the **calcium zincides**, CaZn_{10} and Ca_2Zn_3 respectively, a break at 680° and 12.8 per cent. calcium, corresponding with the compound CaZn_4 , which possibly melts without decomposition, and two eutectic points at 635° and 17 per cent. and 410° and 57 per cent. of calcium respectively. Between 29 per cent. and 56 per cent. of calcium, the compound Ca_2Zn_3 reacts with the fused mass at 431° to form a fourth compound, the composition of which could not be accurately determined, but may be CaZn . At 385° ,

between 52 per cent. and 84 per cent. of calcium, a fifth compound, Ca_4Zn , is produced by reaction of the compound of unknown composition with calcium. Alloys containing up to 6 per cent. of calcium are rather harder than zinc, and are

FIG. 75.—Fusion Curve of Calcium-Magnesium Alloys.

FIG. 76.—Fusion Curve of Calcium-Zinc Alloys.

fairly stable in air and towards water, but with increasing proportion of calcium they darken in the air and act more vigorously on water. The brittleness increases up to 30 per cent. of calcium, and then diminishes. G. D. Roos gave 76.95 Cals. per gram for the heat of fusion of CaZn_{10} ; and 83.5 Cals. for CaZn_4 ; he also gave 199 Cals. per mol for the heat of formation of CaZn_{10} , and 55.6 Cals. for CaZn_4 . W. Jenge, and G. Tammann studied the chemical activity of the alloy. H. Gautier made an alloy of strontium and zinc by the action of sodium on a fused mixture of zinc and strontium chlorides in an iron crucible at a red heat; or better, by heating a mixture of zinc, sodium, and strontium iodide. When heated zinc and strontium volatilize together.

L. Donsky also found that the f.p. curve of cadmium and calcium alloys, Fig. 77, does not show normal maxima, but there are two eutectic points at 319° and 1 per cent. of calcium (components calcium and CaCd_2) and 415° and 71 per cent. calcium (components CaCd_3 and mixed crystals rich in calcium). With between 12 per cent. and 64 per cent. of calcium, the alloys form two layers which react at 685° with formation of the **calcium cadmide**, CaCd ; the latter has a transition point at 635°. At 615°, the compound CaCd reacts with the fused mass rich in cadmium to form a second compound, CaCd_3 . A further break in the cooling curve at 510° appears to indicate a reaction between CaCd and the fused mass to form a third compound, the formula of which may be Ca_2Cd_3 . Alloys containing up to 10 per cent. of calcium are stable in the air, and scarcely act on water; beyond that point, the action on water increases with increase

FIG. 77.—Fusion Curve of Calcium-Cadmium Alloys.

in the proportion of calcium. The brittleness increases rapidly between 10 per cent. and 40 per cent. of calcium, and beyond that point diminishes. W. Jenge, and G. Tammann studied the chemical activity of the alloy. H. Gautier made an

alloy of strontium and cadmium in a similar way to that employed for the strontium-zinc alloy. It was found to oxidize readily in air; to decompose water rapidly; to burn in oxygen or sulphur; and to form strontium hydride when heated in hydrogen, and strontium nitride when heated in nitrogen. It is attacked by chlorine, bromine, iodine, sulphur, and phosphorus. H. Gautier also made an alloy of barium and cadmium in a similar way. Its properties are similar to those of the strontium-cadmium alloy.

J. Parkinson²⁹ prepared an alloy of zinc and magnesium by melting the two elements together. Magnesium was found by C. T. Heycock and F. H. Neville to dissolve readily in molten zinc without any perceptible evolution of heat. O. Boudouard found that if an alloy with 20 per cent. magnesium be treated in the cold for some days with 0.003*N*-hydrochloric acid, pulverulent **magnesium dizincide**, MgZn_2 , remains; while an alloy with 30 per cent. of magnesium when treated with 0.005*N*-ammonium chloride gives pulverulent ZnMg_4 —rapidly when heated, slowly in the cold. C. A. Kraus measured the electrical conductivity of magnesium dizincide. G. Grube denied the existence of ZnMg_4 as a chemical individual. R. de Montgela obtained an alloy of zinc and magnesium by the electrolyses of a conc. soln. of zinc and magnesium chlorides in the proportions 1:2; A. Siemens also investigated this subject. T. L. Phipson, and A. Roussin found that an acid soln. of a zinc salt gives a precipitate of zinc when treated with magnesium; and from a soln. of a neutral zinc salt, A. Commaille obtained a mixture of zinc, zinc hydroxide, and a basic zinc salt. H. N. Warren obtained a magnesium-zinc alloy by the action of zinc-sodium alloy on molten sodium magnesium chloride, or by the electrolysis of the same with a zinc electrode. G. Masing made an alloy of these elements by compressing a mixture of filings under 3000–5000 atm. press. The f.p. diagram, Fig. 78, has been investigated by G. Grube, G. Masing, O. Boudouard, and C. T. Heycock and F. H. Neville. The curve is the simple W-type, and O. Boudouard placed the maximum corresponding with Zn_2Mg at 570° , and G. Grube at 595° . A. J. Berry found that magnesium dizincide can be prepared by distilling the more volatile metal from a mixture of the two metals. The compound itself can be distilled in exhausted glass tubes at temp. lower than the softening point of glass. The lowering of the f.p. of zinc by magnesium was found by

FIG. 78.—Fusion Curve of Magnesium-Zinc Alloys.

C. T. Heycock and F. H. Neville to be greater than with any other metal. The alloys are all white and more or less difficult to polish. The minute structure has been studied by O. Boudouard, and G. Grube. Alloys with 10 per cent. of zinc were said by O. Boudouard to be readily sawn or filed, and by G. Grube, to be malleable when hammered. As the proportion of zinc increases, the alloys become more brittle. G. Grube found most of the alloys to be brittle. The compound Zn_2Mg is not affected by water. J. Parkinson found that the alloys slowly lose their lustre in air. O. Boudouard etched the alloy with potassium hydroxide; C. Montemartini and E. Colonna studied the formation of ammonia when the alloy dissolves in nitric acid. H. Fleck obtained zinc and magnesium iodides and a little magnesium ethyl by treating the alloy with ethyl iodide. N. J. Stepanoff estimated 10,782 Cals. for the heat of formation of a mol of Zn_2Mg , and G. D. Roos estimated 25 Cals. per mol; for the heat of fusion, the last-named gave 65.8 Cals. per mol. H. von Wartenberg computed the heat of formation of MgZn_2 to be 1314 ± 180 cals.; and for the reaction $\text{Mg}_{\text{gas}} + 2\text{Zn}_{\text{gas}} = \text{MgZn}_{2\text{gas}} + 59$ Cals. G. D. Roos gave 24.5 cals.; and W. Biltz and G. Hohorst, 12.6 cals., 5.126 for the sp. gr. at $25^\circ/4^\circ$, and 30.24 for the mol. vol. H. von Wartenberg found that the compound MgZn_2 distils unchanged at 600° ,

but it is completely dissociated at 1300° . If p_1 be the vap. press. of the magnesium; p_2 that of the zinc; and p that of the compound MgZn_2 , $p_1 p_2^2 K = p$, and $\log K = 13000T^{-1} - 3.5 \log T + 2$ (to 4). W. Jenge studied the electrical and chemical properties of the alloys of magnesium and zinc. According to E. Weinwurm, the alloy *electron* contains 80 per cent. of magnesium and 20 per cent. of other metals—mostly zinc. It easily oxidizes in air; is dissolved by acid and salt soln. and tap water; it is not attacked by soln. of caustic alkalis; soln. of cellulose esters dissolve it; it can be cast, forged, rolled, or drawn, and it machines easily; it is a good conductor of electricity.

J. Parkinson prepared an alloy of cadmium and magnesium by melting the two metals together at a dull red heat in a hard glass tube in an atm. of hydrogen. G. Grube, R. Ruer, and O. Boudouard studied the f.p. curve. The latter obtained three maxima corresponding with the **magnesium cadmides**, CdMg (500°), CdMg (565°), and CdMg_{30} (650°), and he claimed to have prepared the first two by the method employed for the corresponding compounds of zinc, Fig. 79. G. Grube

FIG. 79.—Fusion Curve of Magnesium-Cadmium Alloys.

reported that the f.p. curve of the system magnesium-cadmium falls continuously from the m.p. of magnesium to that of cadmium, but shows a slight break at 82.19 per cent. by weight of the latter metal, corresponding with the composition of the compound CdMg ; this substance forms a complete series of mixed crystals with both its components. When the cooling is rapid, the crystals separating between 20 and 95 per cent. of cadmium are not homogeneous, owing to equilibrium between the melted alloy and the crystals not

being established with sufficient rapidity. There is no evidence of the existence of the compounds CdMg_4 and CdMg_{30} mentioned by O. Boudouard. The compound CdMg is greyish-white and slightly harder than cadmium; it becomes oxidized in moist air and is readily acted on by water. G. D. Roos gave 17.7 Cals. per mol for the heat of formation of MgCd , and he estimated that it undergoes association to the extent of 16 per cent.; W. Biltz and G. Hohorst gave 9.2 cals.; and 5.383 for the sp. gr. at $25^{\circ}/4$, and 25.4 for the mol. vol. L. Guillet measured the hardness of these alloys. W. Jengo studied the electrical and chemical properties of magnesium-cadmium alloys; and L. Aitcheson the mechanical properties.

Alloys of cadmium and zinc were prepared by B. Wood;³⁰ and C. T. Heycock and F. H. Neville, and C. R. A. Wright found the two metals mix in all proportions, and G. Hindrichs found that although the molten metals are completely miscible, no compound and no mixed crystals are formed, but the two metals on solidification crystallize separately. E. Macy, H. Gautier, C. T. Heycock and F. H. Neville, N. A. Puschin, and B. E. Curry failed to obtain any sign of chemical combination. The f.p. curve of zinc and cadmium alloys is of the simple V-type. It was investigated by G. Hindrichs, H. Gautier, C. T. Heycock and F. H. Neville, and D. V. Plumbridge. The m.p. of zinc falls from 419° to the eutectic 270° when 82.6 per cent. of cadmium is present; it then rises to 322° , the m.p. of cadmium. The minute structure was examined by most of these investigators. S. Lussana measured the compressibility of zinc-cadmium alloys. G. Masing found that the structure of the alloy obtained by compressing a mixture of finely divided zinc and cadmium between 1000 to 4000 atm. is quite different from that obtained by fusing the metals together. The sp. gr. was investigated by G. Vicentini and D. Omodei, E. Macy, and B. E. Curry; the hardness, by A. V. Saposhnikoff and M. Sacharoff, and N. S. Kurnakoff and A. N. Achnasaroff; the mechanical properties, by W. Voigt

and J. Miller, and O. Meyer; the coeff. of thermal expansion, by G. Vicentini and D. Omodei; the electrical conductivity, by A. Matthiessen, E. Rudolfi, W. Guertler, G. Tammann and K. Dahl, and G. Vicentini and C. Cattaneo; the potential in soln. of sodium chloride, by A. P. Laurie; the e.m.f. of the cell $\text{Zn} \mid \text{ZnSO}_4 \mid \text{Zn}-\text{Cd}$ alloy, by N. A. Puschin; of $\text{Cd} \mid \text{MgSO}_4 \mid \text{Mg}-\text{Cd}$ alloy, by R. Kremann and J. G. Pammer; and the thermo-e.m.f. against lead, by A. Battelli. C. Montemartini and E. Colonna studied the formation of ammonia during the dissolution of alloys of zinc and cadmium in dil. nitric acid. E. Jänecke studied the ternary system, $\text{Mg}-\text{Zn}-\text{Cd}$.

CHAPTER XXXI

MERCURY

§ 1. The History and Occurrence of Mercury

MERCURY is not mentioned by Moses in the Pentateuch, nor by the earlier Greek writers, and H. Kopp,¹ therefore, inferred that the discovery of this element came later than that of gold, silver, copper, tin, lead, or iron. M. Berthelot believed that tin-amalgam and copper-amalgam were known to the ancient Egyptians under the name *asem*. According to S. Seligmann, the discovery by H. Schliemann of a small vessel full of mercury in a grave at Kurna, and estimated to belong to the sixteenth or fifteenth century B.C., shows that this element must have been known a very long time. A. Weiskopf was of the opinion that this element was probably known to the Phœnicians and Carthaginians 700 B.C. In his *Meteorology*, Aristotle, 320 B.C., mentioned mercury—*ἀργυρον χυρόν*, liquid silver—and stated that it must contain much water and air because it resists solidification by cold; and in his *De anima*, Aristotle also referred to its use by the priests. A few years afterwards, Theophrastus, 300 B.C., in his *Περὶ Λίθων*, stated that *ἀργυρον χυρόν* is obtained by rubbing native cinnabar with vinegar in a copper mortar with a copper pestle. Discoveries of stone hammers, arrow-heads, wooden plates, and coins, made around Monte Amiata, Italy, show that these mines were worked for cinnabar by the Etruscans, and later by the Greeks and Romans. These relics are preserved in museums at Sisle and Cornacchino. About the beginning of the Christian era, Dioscorides, in his *De materia medica*, called mercury *ὑδράργυρος*—*ὑδωρ*, water; *ἀργυρος*, silver—and stated that it is obtained by sublimation from cinnabar and charcoal in an alembic or iron pot with a luted *ἄμβλιχ*, that is, a cap to collect the condensed vapour. Evidently, about this time mercury was well known to the Greeks and Romans. Near the beginning of the present era, Pliny, in his *Historia naturalis* spoke of *hydrargyrum* in contradistinction to *argentum vivum*, and, according to J. Beckmann, the first term probably referred to mercury separated from the ore by an artificial process, and the second term signified native mercury. Pliny stated that all substances other than gold float on the surface of the metal; and he added that the mercury can be purified by squeezing it through leather, from which it “exudes like a kind of perspiration.” About the same time, Vitruvius, in his *De architectura*, described the preparation of mercury from cinnabar, and, at the beginning of the seventh century, Isidorus, in his *Origines*, described some properties of the liquid.

Mercury played an important rôle in the work of the Alexandrian and later alchemists, inasmuch as it was regarded as one of the three primitive elements from which all matter was made; and, in particular, they believed a substance resembling mercury, if not mercury itself, to be an essential part of all the metals, and it was sometimes called the mother of metals. Leonardo da Vinci, however, would have none of it, and, in his *Codex atlanticus*, said:

The deceitful interpreters of nature assume mercury to be the common germ of all the metals, forgetting that nature varies its seeds according to the different things which those seeds are meant to bring forth.

According to B. Neumann, the term *mercurius* was first employed by the

alchemists in place of quicksilver. Up to the sixth century, when mercury was regarded as a kind of silver, *quicksilver*, it was represented by the moon-crescent ☾, but, according to M. Berthelot, about this time the symbol for the planet Mercury ☿ was used for quicksilver, and the symbol for Jupiter was reserved for tin—previously, the symbol ☿ was often used for tin. During the alchemical period, mercury was diligently studied, and numerous compounds were prepared and many of the properties were closely examined. Thus, the Latin Geber—in his *Summa perfectionis magisterii*—described the preparation and properties of purified mercury; Albertus Magnus—in his *Compositum de compositis*—synthesized cinnabar, mercuric sulphide; and Thomas Aquinas—in his *Secreta alchemiæ*—studied soln. of metals in mercury to which he applied the term *amalgams*. According to A. Libavius, amalgam is a corrupted form of *μαλάγμα*, but, according to J. Ruska, it is a corrupted form of Greek *μίγμα* with the Arabic prefix *al*, making *almagma*.

G. Agricola regarded mercury as a metal, but others were puzzled by it. A. Libavius, and J. J. Becher classed it among substances—like bismuth, arsenic, sulphur, etc.—which have a relationship with the metals. J. Kunckel said that mercury contains a tough sticky material; H. Boerhaave, R. A. Vogel, and G. L. L. de Buffon emphasized the differences in the physical properties of mercury and those of the common metals; G. Brandt called it a half-metal. The truly metallic nature of mercury was recognized when J. A. Braun, in the winter of 1759–60, at St. Petersburg, found that it could be frozen to a solid metal by cooling with a freezing mixture of snow and nitric acid, and when A. L. Lavoisier showed its elementary nature. The history of mercury has been discussed by G. F. Hildebrandt, A. Rössing, F. X. M. Zippe, G. A. J. Lambert, E. O. von Lippmann, and R. André.

The occurrence of mercury.—Mercury is neither abundantly nor widely distributed; it occurs native, in very subordinate quantities, disseminated in liquid globules or filiform masses in cinnabar deposits as a decomposition product of that mineral, and hence, generally near the outcrop. It rarely occurs in individual globules large enough to allow the mercury to be profitably collected, although considerable quantities have been found in various deposits in California. It has been reported—F. B. de Sauvage,² J. A. C. Chaptal, M. de Serres, and P. G. de Grouville—unaccompanied by cinnabar, in the weathered granite at Mélinot (St. Lo, France), and accompanied by calomel in the strata on which Montpellier (Hérault) stands. It also occurs in silvery-white cubic crystals alloyed with silver, as a native *amalgam*, at Moschel (Rhenish Bavaria), at Rosenau (Hungary), Allemont (Dauphiné, France), Arqueros (Coquimbo, Chili), Almaden (Spain). Analyses of the amalgam range from AgHg_3 to Ag_5Hg_3 . There is also a variety named *arquerie* from Arqueros (Chili) which, according to I. Domeyko, has the composition Ag_6Hg . A specimen of native *gold amalgam*, from Columbia, analyzed by H. Schneider, had $(\text{Au}, \text{Ag})_2\text{Hg}_5$; and one from California, analyzed by F. L. Sonnenschein, had Au_2Hg_3 . W. Vernadsky, E. Halse, and G. Flink have studied the occurrence of the various amalgams, etc.

Mercury is usually obtained from locally concentrated deposits of mercuric sulphide—*cinnabar*, or *cinnabarite*—more or less intermixed with the metallic oxides, earths, bituminous matter, iron pyrites, arsenical or antimonial compounds, and ores of gold, copper, and zinc. Its geological distribution ranges from the oldest to the most recent. It is found as a secondary formation from eruptive rocks, and in deposits from sulphurous springs. Thus, A. Liversidge³ reported mercury and mercuric sulphide in the deposits from the hot springs near Ohaiawai (New Zealand), and G. F. Becker and W. H. Melville in the sinter from Steamboat Springs (Nevada). J. A. Phillips, and J. le Conte and W. B. Rising have discussed the deposits now being formed in the fumaroles near Lake Clear (California). F. L. Ransome has investigated the deposits at Almaden; and E. Wittig, those of Mexico. Some cinnabar is coloured black—*hepatic cinnabar*—by a hydrocarbon called *idrialine*, C_3H_2 , and is called *idrialite*; *coralline earth* is a mixture of cinnabar,

bituminous matter, and about 60 per cent. of apatite, or calcium phosphate.⁴ *Metacinnabarite* is a dimorphous variety of mercuric sulphide, and a variety containing some zinc is called *levigianite*.

The most important deposits of cinnabar in **Europe** are at Almaden (Spain), Idria (Carniola, Austria-Hungary), and Nikitowka (Bachmut, South Russia). The mines at Almaden, Grenada, and Oviedo were described by Theophrastus, 300 B.C.; they were mentioned by Pliny, and Vitruvius; and they are still the most important of those in Europe. The Almaden deposits lie on the upper Silurian shales, and the average ore yields 8-9 per cent. of mercury, while the richest ore runs as high as 25 per cent. of metal. The mercurial exhalations in the hot mines make the mining an unhealthy occupation. The Idria deposits have been worked since 1490; and from the old spoil heaps, it is supposed that the deposits at Nikitowka were worked in ancient times at an undetermined period, and it is estimated to be one of the most important deposits in the world. A deposit fourth in importance occurs at Monte Amiata (Italy). Other subordinate deposits occur at Vallalota near Agorda, Bagno S. Filippo, Saturnia, Fano Monte delle Fate, Causoli, Castiglione, Chiaverese, Albareto, Marguo, and San Donato di Ninea in Italy; in the Avala Hills of Serbia; Spizza, and Nehaj in Dalmatia; at Tristyn in Croatia; Mires, Santander, Tobiscon, and Purchena in Spain; Neumarktel, and Littai in Carniola; Balagna, and Capo Corso in Corsica; Isère, Haute Vienne, and Sevrennes in France; Kongsberg in Norway; and Sala in Sweden. There are exhausted deposits at Wolfstein and Moschellandsberg in the Bavarian Palatinate; at Horowitz in Bohemia; and at Volterra, Cerighani, and Ripa in Italy. In **Asia**, there is an extensive deposit in the provinces of Kweishow, and Hoang Hai in China; Senday in Japan; Ildekansk in Siberia; in Borneo; Java; Sumatra; and near Smyrna. In **Africa**, there are deposits in Algeria and in Tunis. In **America**, the output from the deposits at New Almaden, New Idria, and other parts of California exceeds that of Almaden. Work was begun at New Almaden about 1851. The deposits of Almaden and Idria seem to get richer from above downwards, while those in California are said to get poorer. Cinnabar has also been reported and in some cases worked in Texas, and Oregon; in British Columbia; near Capula, St. Romualdo Pedemal, Carro, Dulces Nombres, Guadalupana, Guadalcazar, Huitzaco, and Zacatecas in Mexico; Huancavelica, Chonta, Cajamarca, and Santa Cruz in Peru; Andacollo in Chili; Tolima in Columbia; La Cruz and Santo Tomé in the Argentine; and at Paranagra, Santa Catherina, Santa Paulo, and Oro Preto in Brazil. The Huancavelica mines of Peru began to produce mercury in quantity about 1571. The mines at Guadalcazar in the province of San Luis Potosi (Mexico) were known to the "Indians" before the discovery of Mexico by Spain. In **Australasia**, cinnabar occurs at Cudgegong, and Noggringa Creek in New South Wales; at Kilkivan in Queensland; and at Omaperese in New Zealand.

The world's production of mercury, in flasks of about 75 lbs., was:

1880	1890	1900	1906	1914	1917
119,168	101,656	99,240	108,120	107,589	122,092

The maximum and minimum prices per flask in 1916 were respectively £18 15s. and £16 12s. 6d., and in 1919 respectively £24 10s. and £15 10s. The pre-war price was about £7 per flask. The production in flasks of about 75 lbs., in different countries, was:

	United States.	Spain.	Austria-Hungary.	Italy.	Russia.	Mexico, etc.
1906 . . .	28,890	37,260	17,130	12,540	6,300	6,000
1914 . . .	16,548	28,000	27,500	31,541	—	4,000
1917 . . .	35,954	25,133	27,500	29,300	500	4,000

The other minerals and ores of mercury are of no economic importance so far as the extraction of the element is concerned. There are the minerals: *tiemannite*, HgSe , which, according to G. F. Becker, was once commercially worked in Utah; *coloradite*, HgTe ; *onofrite*, or *guadalcazite*, $\text{ZnS} \cdot 6\text{HgS}$; *lehrbachite*, or *lerbachite*, $\text{HgSe} + \text{PbSe}$; *calgoorite*, $\text{Ag}_2\text{Au}_2\text{HgTe}_8$; *livingstonite*, $\text{HgS} \cdot 2\text{Sb}_2\text{S}_3$, or $\text{FeS}_2 \cdot \text{HgS} \cdot 4\text{Sb}_2\text{S}_3$; *montroydite*, HgO ; *calomel*, or *horn quicksilver*, HgCl ; *bordosite*, possibly $\text{AgCl} \cdot 2\text{HgCl}$; *coccinite*, HgI_2 , is doubtful, it may be a mercuric chloroselenide; *terlinguaite*, Hg_2OCl ; *eglestonite*, Hg_4OCl_2 ; *magnolite*, Hg_2TeO_4 ; *kleinite*, $3\text{HgO} \cdot \text{HgCl}_2$ or $\text{Hg}_4[\text{O}(\text{NH}_2)_2]_3(\frac{1}{2}\text{SO}_4, \text{Cl})_2$; and *mosesite*, which is similar to kleinite and is a mixture of ammonium mercuriochloride with mercurous sulphate and possibly chloride; *barcenite* is supposed to be a mixture of calcium mercury antimonate and antimonic acid.

Mercurial earths at Guadalcazar are called *acerado*, and *fierroso*. There are mercurial *fahlores* containing some cinnabar—may be up to 18 per cent. Hg —also called *hermesite*, at Ober-Moschel; *schwatzite*, at Tyrol; and *spanoilite*. A Kretschmer found 0.75 per cent. Hg in a sample from Müsen, 1.52 per cent. in one from Kotterbach, 0.80 in one from Brixlegg; and A. d'Achiardi, 3 per cent. in one from Zulfello (Tuscany).

F. Sandberger found mercury in copper; H. Wurtz reported 0.99 per cent. in *animicite*, Ag_6S_6 ; L. E. Rivot, 22 per cent. in a cupric antimonate with mercuric telluride from Chili; F. Field also found mercury in cupric antimonate; A. M. del Rio in zinc selenide; M. Barval reported mercury in Caucasian iron ore; H. Wurtz, 1.04 to 1.11 per cent. in *hunttilite*; P. Collier found 1.30 per cent. of mercury in *stromeyerite* from Arizona; and A. Hilger found 15.79 per cent. of mercury as cinnabar mixed with a stibnite from Mexico. Many varieties of zinc blende have been reported to contain mercury—e.g. by E. Hairs in the blende from Bleyberg; F. L. Bartlett in the blende from Leadville; L. de Launay and G. Urbain in tertiary blendes; 0.02 per cent. in the Rhenish and Swedish blendes; and P. Soltsien, 0.135 per cent. in Asturian blendes.

The literature on the Californian ores has been collected by W. Forstner; * the Oregon deposits, by B. A. Wendeborn; the Arizona deposits, by F. C. Schrader; the British Columbia deposits, by G. F. Monckton; the Idria mines, by A. Schrauf; the Monte Amiata mines, Italy, by A. Verri, P. de Ferrari, B. Lotti, and V. Spirek; the Mount Avala mines of Serbia, by H. Fischer; the Almaden mines of Spain, by H. Kuss; the Huancavelica mines of Peru, by A. F. Umlauff; the deposits of Borneo, by F. Katzer; the Algerian deposits, by M. Dussert; and the principal deposits of the world by L. Demaret. General collections have been made by E. Detienne, E. Fuchs and L. de Launay, A. W. Stelzner and A. Bergeat, R. Beck, F. Beyschlag, P. Krusch and J. H. L. Vogt, and C. Hintze. G. F. Hildebrandt collected the earlier literature.

F. W. Clark thus describes G. F. Becker's views on the origin of mercury ores:

The chief deposits of mercurial ores are all in the neighbourhood of igneous rocks, from which it is highly probable they were originally derived. The deep-seated granites, in his opinion, form the principal source of the mercury. The ore bodies in some cases fill fissures, fractures, or cavities in rocks, the latter being commonly of a sedimentary character; and in other instances the cinnabar forms impregnations in sandstone or limestone. The ores are commonly associated with pyrite or marcasite, sulphur, calcite, barite, gypsum, opal, quartz, and other secondary minerals, and show distinct evidence that they have been brought up from below in soln. In many cases, if not in all, the evidence of hydrous or solfataric origin is very clear. In G. F. Becker's opinion alkaline soln. containing sulphides are the natural solvents of the mercurial compounds, although V. Spirek, describing the deposits at Monte Amiata, Tuscany, suggests that the mercury was first dissolved as sulphate and precipitated later by alkaline polysulphides. For this supposition there seems to be little or no positive evidence. At Idria, A. Schrauf found no indications of the existence of alkaline thermal springs.

C. de Watteville * claimed that the solar spectrum has no mercury lines, and the presence of that element in the sun is doubtful. J. N. Lockyer found mercury lines in the spectra of the cooler stars. J. L. Proust discussed the occurrence of mercury in the waters of the sea. G. F. Becker reported mercuric sulphide in some Californian waters, and F. Garrigou in the Rocher spring water at Saint Nectaire-le-Haut (Pay-de-Dôme), but J. Lefort and E. Willm doubted if mercury is a constant constituent of the Rocher spring. P. E. Raaschou reported mercury in some mineral waters. J. Bardet examined spectrographically the waters of 54 French springs, and found that mercury was rarely present. J. L. Proust, H. M. Rouelle, J. F. Westrumb, F. Wurzer, and J. Kunckel found mercury in sodium chloride, and in sea-water—the test was made by distilling the salt with sulphuric acid, and the latter may have contained mercury. M. Miropolsky found mercury in sulphuric acid; P. E. Raaschou, in copper; L. Houlléviq, in the carbon filaments of incandescent lamps; and E. Wollschlaeger, in *Codeinum phosphoricum*. G. Seyfriedsberger found mercury in the walls and masonry of a mercury kiln. The so-called mercurial soot, or in Almaden *hollines*, and in Idria *stupp*—from the Slavonic *stupa*, dust—is the flue-dust which collects in mercury extraction furnaces, and is in some respects analogous with zinc fume or blue zinc. Stupp consists of a mixture of finely-divided mercury, soot, mercuric oxide, sulphide and sulphate, quartz, etc. It is subsequently treated for the mercury it contains. A. F. G. A. Leymerie found mercury in the roots of the mulberry tree at Valleraugue; and L. Oelkers, in tape-worms from man after treatment with mercurial salve; E. Ludwig and E. Zillner

found very little mercury in the brain and bones, more in the spleen and liver, and still more in the kidneys, and in parts of the large intestine of a man poisoned with mercurial salts. H. Winternitz noted that mercury is partly removed from the system by the urine.

§ 2. The Preparation and Extraction of Mercury

The early processes for the extraction of mercury have already been indicated. They were described by G. Agricola in 1556. In 1719, A. Jussieu¹ described the process of extraction employed at Almaden, and in 1776, B. G. Sage, the process of extraction employed in the Palatinate. In virtually all cases, cinnabar is the only ore from which the metal is extracted, and the simplicity of the reduction is such that extremely poor ores can be profitably worked; the bulk of the mercury in commerce is obtained from ores containing 0.5 to 1.0 per cent. of metal; indeed, in some places, an ore with 0.75 per cent. of mercury is considered to be comparatively rich. The ore is not concentrated by wet processes because cinnabar is so friable that a considerable proportion would be lost by floating off with the water. As a rule, the rich portions of the ore are separated at the mine by spalling, and hand-picking; the poorer ores are classified by screens or trommels into coarse and fine. Each of these grades may be re-classified. The general result is (i) a "rich small ore" running about 6 per cent. of mercury and of a grain size up to 0.32 in. diam.; (ii) a "medium small ore" up to about 1.2 ins. diam. with about 0.6 per cent. of mercury; and (iii) a "poor coarse ore" with pieces between 1.2 and 4 ins. in diam., and running about 0.3 per cent. of mercury. The coarse ore is treated in shaft furnaces both in Europe and in America; the medium ore is treated in shaft furnaces in America, and in shelf or cascade furnaces in Europe; and the fine ore is treated in Europe in reverberatory furnaces. Rich ores are treated in retorts, as in America, or in tile furnaces, as in Europe. Formerly all the furnaces were intermittent, but continuous furnaces are now employed.

Two general methods are available on a large scale for the reduction of cinnabar. The one depends on the oxidation of heated cinnabar by air, mercury vapour, and sulphur dioxide being formed: $\text{HgS} + \text{O}_2 = \text{Hg} + \text{SO}_2$; in the other the cinnabar is heated with lime in a vessel from which air is excluded, calcium sulphide and sulphate are formed, and mercury vapour is set free: $4\text{HgS} + 4\text{CaO} = 3\text{CaS} + \text{CaSO}_4 + 4\text{Hg}$; instead of lime, iron in the form of smithy-scales can be used: $\text{HgS} + \text{Fe} = \text{FeS} + \text{Hg}$. In every case the reactions take place at a temp. exceeding the b.p. of mercury, so that the condensation of the vapour is an essential part of the process. J. F. Booth showed that if the ore is very rich in sulphur, some sulphur vapour may pass on to the condensers and re-form mercuric sulphide. In the air oxidation, the vapour of mercury is largely diluted with sulphur dioxide, nitrogen, oxygen, and generally with the products of combustion; under these conditions, as in the case of zinc, the mercury vapour condenses with difficulty, and more or less mercurial soot, hollines, or stupp is formed, and this requires special treatment in order to recover the mercury. Nevertheless, the condensation of mercury vapour, highly diluted with furnace gases, is more easily effected than is the case with zinc vapour under similar conditions, first because, when sufficiently cooled, mercury passes into the liquid state; and on account of its high sp. gr. it can be separated without

great difficulty. The mercury vapour obtained when the cinnabar is heated with lime or iron in retorts is readily condensed, but under these conditions, only small quantities can be treated at a time, the retorts last for a comparatively short time, the costs of fuel and labour are high, and the workmen are exposed to mercurial fumes when the retorts are cleaned. In the air-oxidation process, the costs of fuel and labour are comparatively small, and the workmen are not troubled by mercurial fumes. The last factor is of paramount importance, and retorting is used only for the treatment of specially rich ores. The retorts first employed were made of clay, and cast-iron bottles were later used, and later still retorts made of cast iron were employed shaped much like those used in the preparation of coal gas. The mouth of the retort dipped under water, so that the process is a kind of *distillation per descensum*. At one time, the reduction with iron was used at Horozowitz in Bohemia, and the lime reduction was used in Idria (Carniola), Rhenish Palatinate, Monte Amiata, at Landsberg (Bavarian Palatinate), Pine Flat (California), and is said to be still in use at Lattai (Carniola). The distillation process in Mexico and Chile has been described by B. Neumann, E. de Riviero, V. Perez-Rosales, etc.

The oxidation process includes an air-combustion and a kind of distillation. In an early form of the process employed at Idria,² the ore was oxidized on perforated stone arches, and the gaseous products passed from the roasting chamber up and down seven condensing chambers, and finally through a turret-shaped chamber into the air. The inclined floors of the condensing chambers enabled the condensed mercury to be readily collected. This furnace is practically obsolete. At Almaden, the gases from the roasting chambers traversed half a dozen series of tubes made up to small cylinders—called *aludels*—open at both ends, and fitting into one another. These were laid on a surface—called the *aludel-bath*—first descending a little and then ascending, and finally directed into a chimney. This furnace, according to H. Kuss,³ was designed in 1633 by L. S. Barba in Huan-cavelica (Peru), and was introduced into Almaden (Spain) by M. Bustamente in 1646, whence it is sometimes called *Bustamente's furnace* or the *aludel furnace*. In spite of many attacks this furnace has maintained itself up to the present. C. de Kalb has described the extraction of mercury at Almaden.

The continuous shaft furnaces are of two types: (i) Those without inclined shelves used for large ore, and exemplified by *V. Spirek's shaft furnace*,⁴ and *F. Novak's shaft furnace* without an external fireplace, and A. Exeli's shaft furnace with external heating; (ii) those with inclined shelves used for medium and fine ore, and exemplified by *Scott's shaft furnace*, and *Litchfield's shaft furnaces*. The *Czermak-Spirek Schüttröstöfen* is a kind of *four à cascade* or tile furnace with ridges so arranged as to make it behave like a group of low shaft furnaces or a multiple-hearth reverberatory furnace. The modification without ridges is a reverberatory furnace proper, and is used for dust, ores which decrepitate, and for the treatment of stupp.

V. Spirek's shaft furnace, illustrated by Fig. 1, is a square shaft of ordinary firebrick braced with angle iron and tie-rods, and supported on columns. The bottom of the furnace is about 5 ft. above the floor-line so that a truck can be run underneath to receive the spent ore when the sloping iron firebars are moved. The charge is a mixture of coarse ore with about 2 per cent. of charcoal, and it is fed into the furnace through the hopper. The outlet pipes lead the mercurial vapour, etc., to the condensers. These consist of six or more series of pairs of vertical pipes of cast iron, or glazed stoneware of elliptical cross-section and supported on a wooden framework. Each pair of pipes is about 8 ft. in length, and 20–24 ins. diameter, and is cemented at the bottom into a V-shaped receiver with the lower end open, and dipping into about 2 ins. of water in an iron tank in which mercury and stupp collect. Each pair of pipes is connected with the next by a cap-piece provided with a man-hole. The pipes are cooled with water. The gases which leave the condensers pass into a large wooden condensing or dust chamber which is divided by baffle walls so that the gases follow a zig-zag course. This chamber has a sloping floor and gutter to allow any free mercury deposited from the gases to run on to a collecting pan. The exit gases pass from the condensing chamber to the fan and chimney-stack. Every five or ten days there is a clean-up of the tubes with scrapers, brushes, and a jet of water, in order to collect the accumulated stupp.

Mercury is obtained from gold and silver amalgams by distillation. G. H. Mann⁵ also describes the recovery of mercury from amalgamation residues. The recovery of

FIG. 1.—V. Spirek's Shaft Furnace and Condensers for Mercury.

mercury from stupp follows on the lines employed for finely-divided ores, and is discussed by C. Schnabel, F. Pilz, G. Goldschmidt and M. von Schmidt, F. Janda, A. Harpf, A. Weiskopf, E. Teuber, etc. The extraction of mercury from fahl-ores has been discussed by C. Schnabel, H. Wedding, J. Schabus, etc. All the commercially successful methods for the extraction of mercury are dry processes; **wet processes** have been proposed, but have met with no economic success. For example, G. Kroupa,⁶ C. A. Winkler, and R. von Wagner have proposed to

extract mercuric sulphide from its ores by a soln. of an alkali sulphide containing caustic alkalis; R. von Wagner recommended a soln. of barium sulphide, or an aq. or hydrochloric acid soln. of bromine; and T. P. Sieveking proposed a soln. of cuprous chloride in sodium chloride in the presence of a granulated alloy of zinc and copper. The cinnabar is decomposed, $2\text{CuCl} + \text{HgS} = \text{CuCl}_2 + \text{CuS} + \text{Hg}$, and the mercury amalgamates with the zinc-copper alloy, from which it is recovered by distillation.

The **electrolytic methods** have not been economically successful. A. von Siemens,⁷ and B. Szilard electrolyzed a soln. of mercuric sulphide in a soln. of hydrosulphide of calcium, barium, strontium, or magnesium; O. Dammer also suggested electrolyzing a soln. of mercuric sulphide in dil. hydrochloric acid (1 : 10) or in an aq. soln. of sodium chloride.

The reduction of mercury from mercury compounds.—E. Reichardt⁸ noticed that precipitated mercurous and mercuric arsenates gradually decompose into mercurous oxide and mercury. M. C. Lea found that by pressing with a pestle in a mortar mercuric and mercurous chlorides, mercuric iodide, and mercuric oxysulphate and oxychloride are decomposed. Several mercury compounds decompose when heated—e.g. the oxide, sulphide, chloride, etc. H. Rose found that many mercury salts—e.g. mercurous succinate—are gradually decomposed by boiling with water. M. Guerbet found that a soln. of mercuric gluconate is likewise decomposed. P. and M. M. Richter showed that mercurous cyanide decomposes when allowed to stand for some time, or when boiled with water: $2\text{HgCy} = \text{Hg} + \text{HgCy}_2$. L. O. Helmers found aq. soln. of mercurous ichthyolsulphonate behaved similarly. According to J. Riban, a soln. of mercuric acetate in a tube at 175° forms mercury, carbon dioxide, and acetic acid.

Mercuric oxide was found by W. Müller to be reduced to the metal by **hydrogen** at 220° – 230° ; and O. Schumann found mercuric sulphate to be similarly reduced. N. N. Beketoff, and E. Cohen found that hydrogen precipitates mercury from an aq. soln. of its salts—the press., said C. Brunner, must be over 100 atm. S. Cooke precipitated mercury from soln. of mercuric nitrate by treatment with hydrogenized platinum; and B. Neumann likewise obtained mercury and mercurous chloride from an aq. soln. of mercuric chloride. A. C. Chapman found hydrogenized palladium

reduces soln. of mercuric salts partly to mercurous salts, and partly to metal. F. Utz, and M. Kohn reduced mercuric compounds by the action of **hydrogen peroxide** in alkaline soln., and W. Kwasnik used **barium dioxide**. According to A. Vogel, soln. of mercurous and mercuric salts are reduced to the metal by **sulphur dioxide**; and, according to O. Brunck, **sodium hyposulphite**, $\text{Na}_2\text{S}_2\text{O}_4$, reduces mercury salts to the metal, which is converted into sulphide by an excess of the reducing agent. J. Myers converted mercuric chloride and mercurous nitrate soln. to the metal by means of **potassium hydrosulphide**, KSH. J. Keir found **ferrous sulphate** and **stannous chloride** can reduce mercury salts to the metal. K. Voit reduced mercury compounds by fusion with **alkali carbonates** or **alkali hydroxides**; and F. Janda by heating them with **iron oxide**.

W. R. Hodgkinson and C. C. Trench passed **ammonia** over heated mercuric sulphate and obtained mercury. A. Thum, and W. Lossen found **hydroxylamine** rapidly reduced mercuric oxide to the metal. E. Knövenagel and E. Ebler found hydroxylamine salts and **hydrazine salts** reduced alkaline soln. of mercuric salts and also soln. feebly acidified with acetic acid. T. Curtius and F. Schrader, A. Purgotti, E. Rimini, and P. Jannasch and W. Bettges also studied the reduction with hydrazine salts. An alcoholic soln. of mercuric cyanide is reduced by **stibine**. B. E. Howard reduced mercury compounds to the metal with **hypophosphorous acid**. A. Gutmann reduced mercury fulminate with an alkaline soln. of **arsenious acid**; I. Pouget with **potassium thioantimonite**; and P. Pascal, with **sodium ferric pyrophosphate**.

A. C. Becquerel reduced mercuric oxide by heating it with **carbon**—*vide infra*. N. Tarugi reduced mercuric compounds by heating them with **calcium carbide**. Many organic compounds reduce mercury salts to the metal, and the reaction is often accelerated by heat or by exposure to light. Thus, A. Vogel found **cane sugar** reduced soln. of mercurous nitrate to mercury and a little mercuric oxide; F. Soxhlet reduced alkaline soln. of mercury salts to the metal. J. Stern and S. Fränkel used an alkaline soln. of **invert sugar**; and J. von Liebig, and C. Knapp reduced an alkaline soln. of mercuric cyanide completely to the metal, by means of **grape sugar**. F. Göbel and P. A. von Bonsdorff found **formic acid** and alkali formates reduce mercury compounds to the metal. O. Loew, and E. Feder have studied the reduction of mercury compounds with **aldehyde**, J. M. Eder investigated the reducing action of **potassium ferrous oxalate** on mercuric salts. C. K. von Reichenbach, of **creosote**; M. J. B. Orfila, **turpentine**; M. T. Lecco, and W. Brunetti, vegetable and animal substances; G. Bizio, **gelatine**; etc. H. Moissan reduced mercurous chloride by heating it to 700° with **boron**.

The metallic precipitation of mercury.—According to N. W. Fischer,⁹ copper, zinc, cadmium, arsenic, antimony, bismuth, tin, lead, and iron precipitate mercury from soln. of mercurous nitrate; with copper, zinc, cadmium, lead, and bismuth, the precipitation is complete in 24 hrs., but with the other elements, some mercury remains in soln. In some cases a white or yellow precipitate—*e.g.* bismuth and lead—is formed at the same time. If a soln. of mercuric nitrate is employed, the action is slower, the salt is first reduced to mercurous nitrate, and basic salts are precipitated with copper, zinc, cadmium, bismuth, antimony, and lead. With soln. of mercuric chloride, zinc, cadmium, and nickel precipitate mercury rapidly and completely, with iron the action is slower, and slower still with copper, bismuth, and lead—in most cases also some mercurous chloride is precipitated at the same time; with zinc and cadmium, an amalgam is formed. P. Schorigin found that mercury is obtained when mercuric ethyl is treated with **sodium**; and at 100° , E. Frankland and B. F. Duppa observed that the mercury in this compound is completely displaced by zinc, and more slowly and not completely by cadmium, copper, silver, gold, bismuth, and iron. E. Alexander found that mercury is displaced from a soln. of mercuric chloride in ethyl acetate by **aluminium**, and magnesium, and partially by copper, zinc, tin, lead, antimony, and bismuth.

When **copper** is immersed in a soln. of a salt of mercury, the metal becomes

covered with a grey film which appears silvery white when rubbed between paper. H. Reinsch found that copper is coated by a film of mercury in a soln. of mercuric chloride (1 : 1000) in the presence of hydrochloric acid ; with a dilution of 1 : 50000, no film is produced in the cold if the acid be absent, but when boiled the copper is coloured golden-yellow, and if the acid be present, a grey film of mercury is produced. A. Vogel found the film is lost when the copper stands exposed to the air for 12 hrs. T. W. Richards and S. K. Singer obtained a quantitative precipitation of mercury from a soln. of mercuric nitrate with not too great an excess of acid ; and, according to W. Odling, and H. G. Magnus, the precipitation occurs with soln. of mercuric chloride, but not with soln. of mercuric sulphate or nitrate. M. Caucal, and A. Vogel obtained mercurous chloride as well as mercury from soln. of mercuric chloride. N. W. Fischer also found that mercury is reduced from a soln. of a mercurous salt by brass. According to A. Ogg, dil. soln. of mercurous salts are reduced by **silver**, and, according to J. N. Brönsted, 1.29 to 1.55 Cals. are absorbed per mol. of mercurous chloride, and more at a higher temp. C. Zenghelis found that silver foil reduces a cold sat. soln. of mercuric nitrate, and in 2 hrs. at 80°, a soln. of mercuric chloride is reduced to mercurous chloride. G. Campani found that in a few hours finely divided silver completely reduces to mercury an aq. soln. of mercuric chloride, or an aq. soln. of potassium iodide and mercuric iodide. G. McP. Smith also noted the reductions of soln. of mercuric chloride, cyanide or nitrate, mercurous nitrate, or of potassium mercuric cyanide. A. Vogel found that with mercuric chloride soln., some mercurous chloride is precipitated as well, and G. Wetzlar noted the production of silver chloride. E. Cohen, and A. and L. Lumière and A. Seyewitz studied the bleaching of photographic negatives in consequence of the reaction : $\text{Ag} + \text{HgCl}_2 = \text{AgCl} + \text{HgCl}$. N. W. Fischer found that alloys of silver with tin, lead, zinc, and copper reduce soln. of mercurous salts to mercury. G. Bredig and J. Weinmayr noted that **gold** precipitates mercury from a conc. soln. of potassium mercuric cyanide ; and if an alkaline soln. of mercuric chloride be treated with colloidal gold, mercury is precipitated on the particles of gold.

According to A. Schmidt, and K. Seubert, **magnesium** precipitates from neutral soln. of mercuric chloride, a mixture of mercurous chloride, mercury, and mercuric oxide, and the precipitation is complete, only after a prolonged boiling ; in acid soln., more mercury is mixed with the mercurous chloride. If mercurous chloride suspended in water be boiled for several hours with magnesium filings, mercury mixed with a little mercurous oxide is **quantitatively** obtained—in the presence of hydrochloric acid, the latter is not formed. S. Kern found that magnesium with a conc. soln. of mercuric chloride furnishes hydrogen and mercuric oxide ; and H. Mouraur noted that the separation of mercury by the magnesium treatment is attended by the evolution of hydrogen. D. Vitali found that with magnesium a conc. soln. of mercuric chloride gives hydrogen, mercuric oxide and oxychloride, mercurous oxide and the metal ; with mercuric cyanide, magnesium cyanide is formed which decomposes at a low temp., forming magnesium oxide, which then forms some mercuric oxide, and a part of the evolved hydrogen reduces the mercuric cyanide, and oxide to mercury. According to H. Rose, **zinc** does not reduce an aq. soln. of mercurous sulphate, or mercurous chloride suspended in water ; zinc precipitates all the mercury from soln. of mercuric sulphate or nitrate acidified with sulphuric or nitric acid, or from neutral soln. of mercuric chloride, without amalgamation, but a soln. of mercuric chloride acidified with hydrochloric acid rapidly amalgamates the zinc. E. Ludwig found zinc precipitates all the mercury from urine. R. Varet found that **aluminium** precipitates mercury from aq. soln. of mercuric cyanide, and A. Cossa, from aq. soln. of mercuric nitrate or chloride—some aluminium hydroxide and hydrocyanic acid are produced in the former case—the mercury unites with the aluminium, forming an amalgam which vigorously decomposes water, and rapidly oxidizes in air. V. Borelli stated that aluminium is better than magnesium or zinc for reducing mercury from cyanides. J. Klaudy found

that with a soln. of mercuric chloride, aluminium amalgam is formed which decomposes water, forming aluminium hydroxide; F. Regelsberger noted the formation of aluminium hydroxide in this reaction. C. Reichard noted that insoluble or sparingly soluble mercury compounds react with aluminium feebly or not at all.

L. F. Boeck, and M. Lazowsky found that **carbon** immersed for two days in a soln. of mercurous nitrate becomes covered with globules of mercury. N. W. Fischer found that with a soln. of mercurous nitrate, **tin** becomes covered with a brown powder which continually deepens in colour and after a few days is resolved into globules of mercury. According to J. Smithson, if a piece of tin in contact with a gold plate is introduced into a soln. of a mercuric salt acidified with hydrochloric acid, the tin forms an amalgam with the precipitated mercury. J. H. van den Broek obtained a similar result with a tin-platinum couple. E. Rupp reported that **iron** quantitatively precipitates mercury from mercuric salts, and M. J. B. Orfila, that iron decomposes mercurous salts at ordinary temp.; but N. W. Fischer said that iron has no action on a soln. of mercurous nitrate because the metal becomes passive, and L. Gmelin added that this applies to a conc. soln. of mercurous nitrate, but from a dil. soln. of the nitrate or acetate, mercury is readily precipitated. R. Varet found that iron is a stronger reducing agent than **nickel**, and that the latter metal reduces an aq. soln. of mercuric chloride to mercurous chloride, and partially to mercury—if air is present some nickel sesquioxide is formed. E. F. Smith observed that **molybdenum** reduces soln. of mercuric chloride, potassium mercuric iodide, and mercurous sulphate to the metal. E. F. Smith found that **tungsten** slowly reduces aq. soln. of mercuric chloride to the mercurous chloride, but soln. of mercurous sulphate and potassium mercuric iodide are only partially reduced. C. Zimmermann found that **uranium** precipitates mercury from a soln. of mercuric nitrate, and a mixture of the metal and mercurous oxide from a soln. of mercuric chloride.

According to H. Davy, when **phosphorus** vapour is passed over heated mercuric chloride, it forms phosphorus trichloride and the metal. L. F. Boeck, and N. W. Fischer observed that phosphorus precipitates mercury from a soln. of a mercurous salt. M. J. B. Orfila found that **arsenic** precipitates mercury from mercurous nitrate or sulphate at ordinary temp., and N. W. Fischer, that **antimony** does not precipitate mercury from a soln. of mercuric chloride. The action of **bismuth** is indicated above.

The electro-deposition of mercury.—The quantitative precipitation of mercury by the electrolysis of soln. of its salts is discussed in several text-books—e.g. those of A. Fischer,¹⁰ A. Classen, and E. F. Smith—and the subject has been discussed by F. Rüdorff, H. J. S. Sand, J. B. Hannay, C. H. Wolff, A. Fischer, C. Luckow, Z. Karaoglanoff, etc. In the electrolysis of mercurous nitrate soln., N. W. Fischer obtained some peroxide, and basic nitrate. A. Classen, and L. de la Escosura showed that the electrolysis of aq. soln. of sodium chloride or hydrochloric acid in which insoluble mercury compounds—mercuric sulphide, mercurous chloride, etc.—are suspended yield mercury; F. W. Clarke also found that mercury is precipitated from a soln. in which the basic sulphate is suspended. Electrodes for the electrolysis of mercury salt soln. have been investigated by A. Classen, S. K. Singer,¹¹ and many others.

An electrolyte acidified with *nitric acid* was employed by A. Classen, H. Freudenberg,¹² E. F. Smith and co-workers, R. O. Smith, H. J. S. Sand, etc.; an electrolyte acidified with *sulphuric acid*, by F. W. Clarke,¹³ L. G. Kollock, A. Fischer, E. Bindschedler, and B. Neumann; *ammoniacal* electrolytes, by H. J. S. Sand,¹⁴ and M. François; an electrolyte containing *cyanides* by E. F. Smith¹⁵ and co-workers, F. Glaser, E. Bindschedler, A. Classen, etc.; a soln. of *ammonium* or *potassium thiocyanate* by L. K. Frankel;¹⁶ a soln. of mercuric sulphide in *sodium sulphide* by E. F. Smith and co-workers, L. G. Kollock, A. Fischer, R. O. Smith, G. Vortmann, etc.;¹⁷ a soln. of mercuric chloride in one of *potassium iodide*, by G. Vortmann;¹⁸ a soln. of *sodium* or *ammonium phosphate* in one of *ammonia* or

ammonium carbonate, by F. Rüdorff, A. Brand, H. M. Fernberger and E. F. Smith, etc.;¹⁹ a soln. of a mercury salt in an excess of a soln. of *ammonium oxalate*, by A. Classen, G. Vortmann, and A. Fischer;²⁰ a soln. of a mercury salt in an excess of ammonia and *ammonium tartrate*, by G. Vortmann, S. C. Schmucker, and F. Rüdorff;²¹ and a soln. of *mercuric chlorate*, by F. G. Mathers and A. F. O. Germann.²²

The purification of mercury.—Mercury should leave no residue when dissolved in nitric acid, or when fused with sulphur and sublimed in a glass flask; and when agitated with dry air, it should not yield any black powder. When contaminated with foreign metals, etc., mercury becomes *extinguished, sickened, or deadened*. Consequently, when a globule of mercury is made to run down a gently inclined surface, it should retain its spheroidal form, and not "leave a tail." According to M. Meier,²³ the "tail" consists largely of an amalgam of foreign metals with much adherent mercury. According to C. Michaelis, the electrical conductivity is a very sensitive test for the purity of mercury, and G. A. Hulett and H. D. Minchin state that this method will detect the presence of one part of zinc in 10 billion parts of mercury. Impurities mechanically mixed with the mercury can be removed by filtration by press, or suction through leather, or through perforated paper as recommended by L. Pfaundler, G. F. Hildebrandt, G. Vulpius, etc. Several methods have been proposed for the more or less incomplete purification of mercury, and some of these rapid processes are useful in a laboratory where a freely flowing liquid for confining gases, etc., is required, and not necessarily a highly purified metal for chemical operations. W. C. Röntgen has discussed the preparation of mercury presenting a clean surface.

In the method of oxidation a stream of air is drawn through the liquid, and many foreign metals associated with the mercury are oxidized and the grey pulverulent mixture of oxides can be removed by filtration through leather as recommended by J. M. Crafts, L. C. Barreswil, J. J. Berzelius, P. Baumann, E. Maumené, etc. The mercury can also be shaken with certain liquids which oxidize and in some cases dissolve the impurity—thus, G. Branchi recommended agitating the impure mercury for some days with sulphuric acid, or boiling the impure mercury with $\frac{1}{87}$ th of its weight of mercurous nitrate dissolved in a small quantity of very dil. nitric acid; W. Ostwald and R. Luther, and T. W. Richards and G. S. Forbes, a 5 per cent. soln. of mercurous nitrate mixed with some nitric acid; C. Michaelis, shaking with sulphuric acid mixed with a little nitric acid until the mercury was broken up into small globules; G. L. Ulex and H. Wild, a soln. of ferric chloride of sp. gr. 1.48; L. J. Desha, one per cent. nitric acid; G. A. Hulett and H. D. Minchin, an excess of mercurous sulphate in dil. sulphuric acid (1 : 10); J. W. Brühl, W. Kerp, G. McP. Smith, and W. Bolton, a soln. of 5 grms. of potassium dichromate in a litre of water acidified with a few c.c. of sulphuric acid; F. G. Voigtel, a boiling soln. of mercuric chloride in a clean iron vessel—but G. C. Wittstein said this process is not good because mercurous chloride is formed; W. R. Forbes, charcoal sat. with oxygen gas; H. W. F. Wackenroder, a soln. of hydrochloric acid mixed with one-eighth vol. of sulphurous acid; and W. Bettel, a dil. soln. of potassium cyanide in the presence of sodium peroxide—it is claimed that this treatment removes gold, zinc, tin, lead, copper, and iron, and leaves the mercury of a higher degree of purity than fractional distillation. In the shaking process, the surface of contact between the metal and the soln. is relatively small, and a long shaking is required to dissolve the impurities present in the mercury; L. Meyer, and A. Weinhold therefore proposed allowing the mercury to fall in a fine stream one or more times through a long column of mercurous nitrate. Several forms of apparatus have been proposed—e.g. by B. Karsten, C. Harries and F. Evers, K. Kaehler and M. Martini, C. J. Moore, G. A. Hulett and H. D. Minchin, J. H. Hildebrand, L. J. Desha, etc. In some of these forms, the mercury is raised by suction to the upper part of the apparatus so that the process is continuous, and the mercury descends through the column of liquid a number of times.

W. Jäger, and F. A. Wolff and C. E. Waters purified mercury electrolytically

by making the impure mercury the anode in a soln. of nitric acid; J. H. Hildebrand added that the process occupies much time, requires efficient stirring, and is not particularly efficacious. According to C. Michaelis, the separation of mercury from admixed impurities is complete if the impure mercury be distilled in vacuo. with the surface of the metal at rest; if the press. be insufficiently low, and the surface of the mercury turbulent, some spray of impure metal is carried along with the vapour to the receiver. Boiling mercury is liable to spirting—covering the impure mercury in the retort with a thick layer of iron filings in order to arrest the spray has been recommended; and A. F. L. Dörfurt recommended distilling the mercury with one-tenth its weight of cinnabar; he believes that the sulphur retains the foreign metals in the retort. H. Violette recommended distilling silver-amalgams in a current of superheated steam. Even if bumping be prevented it is probable that some zinc, cadmium, lead, tin, bismuth, and copper can vaporize with the mercury. V. Meyer has said:

It is commonly assumed that mercury can be purified by distillation, but, even after three distillations, much impurity remains. It is therefore possible that the mercury vapour carries with it the vapours of other metals as when substances are distilled in a current of steam, or that the impure mercury is mechanically carried forward as spray. In order to determine which of these possibilities is correct, mercury was mixed with a number of metals—lead, bismuth, tin, sodium, and copper—and the mixture distilled first from a porcelain retort and then repeatedly distilled from a glass retort. After twelve distillations, no trace of residue remained in the glass retort, and the distillate gave no residue when two grams of the metal were dissolved in nitric acid, the soln. evaporated, and the residue calcined in a weighed platinum dish.

G. A. Hulett and H. D. Minchin have shown that unless mercury is distilled in a current of air and with no bumping, the more volatile metals like zinc and cadmium are not removed. The distillation process, and various forms of mercury still have been recommended by L. C. Barreswil, W. D. Bohm, H. M. Chance, J. W. Clark, L. Dunoyer, W. R. Dunstan and T. S. Dymond, F. Friedrichs, F. A. Gooch, G. F. Hildebrandt, B. Karsten, B. Lambert, R. Leeds, L. Meyer, N. A. E. Millon, H. N. Morse, B. Nebel, J. Pollak, F. J. Smith, A. Weinhold, J. Wetzel, A. W. Wright, etc. C. T. Knipp heated the mercury to be distilled by striking an arc between the surface of the mercury and each of two electrodes. The mercury was kept in vacuo, and the mercury in the interior of the glass vessel was in communication with that outside. G. A. Hulett recommended distilling the mercury at about 200° in a distillation flask so arranged that a stream of nitrogen or carbon dioxide was drawn through a fine capillary tube below the surface of the mercury, while the interior was under a press. of 25 mm. An amalgam sat. with silver gave a distillate with one of silver in 1,000,000 parts of mercury, and no silver could be detected in the second distillate; a gold amalgam likewise gave a first distillate with 27 parts of gold in 1,000,000,000 parts of mercury, and no detectable amount of gold in the second distillate; similarly, the first distillate of a platinum amalgam contained one of platinum in 100,000,000 parts of mercury.

In the more strictly chemical methods of purification, the mercury is converted into some salt and the purified product is reduced. Thus, C. F. Mohr heated purified mercuric oxide, and obtained a product covered with a film of reproduced oxide. This was purified by shaking with dil. sulphuric acid. G. N. Lewis and R. F. Jackson, and V. Meyer also obtained mercury from the purified oxide. G. F. Hildebrandt heated the purified sulphide or chloride with one part of lime or iron filings—preferably the former.

Colloidal mercury.—If mercury be agitated with water, ether, turpentine, acetic acid (R. Böttger),²⁴ or various salt soln.—calcium or ammonium chloride, sodium nitrate, etc. (N. A. E. Millon)—aq. mercuric chloride or dil. nitric acid (F. B. Hofmann), garlic juice (M. N. Banerjee), or if it be triturated with sulphur, antimony sulphide, sugar, grease, etc., even in vacuo, the mercury is converted into a grey emulsion—*athrops per se*—which consists of minute globules of mercury separated by another medium. The particles coalesce by running together when the

medium is withdrawn, so that the mercury in the emulsion is not sickened mercury—a subject discussed by L. V. Brugnatelli, L. J. Proust, J. Roux, I. Walz, etc. F. V. Bärensprung stated that some of the mercury in grey mercurial ointment is in the state of mercurous oxide—the older the ointment the greater the proportion of black oxide. By first extracting the fat with ether, the oxide can be washed from the residue by water acidulated with sulphuric acid. M. Donovan and K. Voit assumed that mercurous salts of the fatty acids were formed, but A. J. von Oettingen showed that neither mercurous oxide nor the fatty acid salt is present; and C. Barfoed showed that the finely divided mercury does not oxidize in air at ordinary temp. The grey powder is an emulsion consisting of finely divided mercury suspended in the medium. J. Sen stated that finely divided mercury is grey not black. The particles of mercury in grey mercurial ointment cannot be distinguished by the eye alone, and, according to C. G. Ehrenberg, they are nearly uniform in size and range between 0.001 and 0.002 mm. in diam.

Colloidal mercury has been obtained by A. Westgren,²⁵ A. Schereschewsky, A. Gutbier and G. L. Weise, I. Nordlund, J. Billitzer, H. Finger, L. Egger, and F. Haber, by electrolysis, or by cathodic disintegration. The preparation of the colloid by the action of liquid ammonia on mercuric chloride was described by W. Weyl,²⁶ and J. Bronn; by the action of aq. ammonia on a dil. soln. of mercurous nitrate or mercuric chloride in 5 per cent. gelatine, by C. A. L. de Bruyn; by the reducing action of hydrazine salts by A. Gutbier and G. Hofmeier,²⁷ R. May, and A. Lottermoser; by hydroxylamine in the presence of sodium resinate, by A. Westgren; by the action of stannous salts by A. Lottermoser,²⁸ M. Höhnel, J. L. Mewburn, J. Billitzer, and C. A. L. de Bruyn; by the action of colloidal gold, by J. Weinmayr,²⁹ and G. Bredig and W. Reinders; and by the action of salts of protalbinic or lysalbinic acid, by G. Amberger,³⁰ and M. K. Hoffmann. The latter reduced the soln. of a mercury salt by the action of dil. soln. of alkali hydroxide or carbonates followed by dialysis; A. Lottermoser, with ammonium citrate; J. Meyer, with sodium hyposulphite, $\text{Na}_2\text{S}_2\text{O}_4$; A. Gutbier, with hypophosphorous acid; P. Pascal, with ferrous pyrophosphate; F. Küspert, with water-glass and formaldehyde; F. Henrich, with pyrogallol; and A. Dering, with triglycerides; and H. N. McCoy and co-workers, by the electrolysis of cold soln. of tetramethylammonium chloride in absolute alcohol, and a mercury cathode—the tetramethylammonium amalgam decomposes when treated with water, forming colloidal mercury. The *hyrgol* of commerce is colloidal mercury containing 73–80 per cent. of the metal. C. Foa and A. Aggazzotti studied the oxidizing action of colloidal mercury in the presence of hydrogen peroxide. I. Nordlund examined the properties of mercury hydrosols prepared by different processes.

§ 3. The Physical Properties of Mercury

At ordinary temp. mercury is a coherent, mobile, silvery-white liquid, which has very little tendency to adhere to glass. According to L. H. F. Melsens,¹ the colour of very thin layers of mercury in transmitted light is blue with a violet tinge; and, according to F. P. le Roux, the vapour of mercury is blue. G. F. Hildebrandt said that mercury has no odour, and that it *schmerkt metallisch*. H. B. Dixon found that chemically inert gases may be confined over mercury without any appreciable change in volume, showing that the metal is not permeable to these gases. M. Faraday's observation that gases could escape when confined in glass jars in a pneumatic trough over mercury has not been confirmed. Mercury

freezes to a crystalline mass which, according to T. des Coudres, is anisotropic. L. Bleekrode described the freezing of mercury by the aid of solid carbon dioxide; B. Schwalbe used a mixture of solid carbon dioxide and ether. R. Walker stated that the frozen solid consists of octahedral and acicular **crystals**; and that the crystalline mass is a ductile metal with a granular fracture. The crystals have not been so closely investigated as those of the other members of the zinc family of elements; C. F. Rammelsberg stated that the solid metal has a cubical cleavage. According to N. A. Puschin, tin and cadmium amalgams crystallize in the hexagonal system, and the position of mercury in the periodic system with beryllium, magnesium, zinc, and cadmium, all of which form hexagonal crystals, makes it probable that mercury crystals will prove to be hexagonal. M. Volmer studied the growth of the crystals. N. Alsen and G. Aminoff found that the **X-radiogram** of mercury at the temp. of solid carbon dioxide, corresponded with a hexagonal cell containing four atoms and having $a=3.84$ Å., and $c=7.24$ Å. The X-radiogram of mercury, taken by L. W. McKeehan and P. P. Cioffi, agrees with a rhombohedral space lattice with an axial ratio $a:c=1:1.94$.

The physical properties of mercury have been the subject of numerous investigations. H. Fritz,² and A. Schulze have made collections of the physical constants of this element. The Arabic manuscript of Abu-r-Raihan, *The Book of the Best Things*, written about the tenth century, and described by H. C. Bolton, and J. J. Clément-Mullet, has a table of **specific gravity** of 19 substances, and it includes liquid mercury, with a sp. gr. 13.58, which is very near the value accepted to-day. In the Arabian manuscript *Book of the Balance of Wisdom*, written by Al-Khazini in the years 1121–1122 A.D., and described by H. C. Bolton, and N. Khanikoff, 13.56 is given for the sp. gr. of mercury.

G. D. Fahrenheit gave 13.575; P. van Muschenbroek, 13.550; R. Boyle, 14.000; H. Cavendish and M. J. Brisson, 13.5681; J. B. Biot and D. L. J. Arago, 13.588597; C. J. B. Karsten, 13.5592; J. Crichton, 13.568 (15.5°); R. Scholz, 13.586; H. Schiff, 13.603 (12°); P. Volkmann, 13.5953 (0°); H. Kopp, 13.595 (0°); B. Stewart, 13.594 (13.6°) in vacuo; A. T. Kupffer, 13.5886 (4°/4°), and 13.535 (26°/4°); A. W. Warrington, 13.59563 at 0°; J. Biddle, 13.613 (10°); A. Matthiessen, 13.573 (14.5°); and H. Wild, and W. Marek, 13.5956 (0°/4°).

G. Vicentini and D. Omodei found 13.6902 at -38.85° —i.e. for the liquid at the f.p. G. G. Hällström obtained 13.6078 (0°), and 12.810 at the b.p.; and H. V. Regnault, 13.582 (5°–10°), 13.570 (10°–15°), 13.558 (15°–20°), and 13.59593 at 0°. R. Lenz and N. Restzoff obtained the extremes 13.59869 and 13.59810 for determinations with thirteen different samples of mercury. M. Thiesen and K. Scheel gave 13.59545 at 0°. The best representative value of this mass of discrepant data may be taken as 13.596 at 0°. R. Walker found that the solid metal is specifically heavier than the liquid because it sinks therein. J. A. Schultze gave 14.391 for the sp. gr. of solid mercury; G. G. Hällström, 14.333 at -40° ; J. Biddle, 14.485 at -60° ; J. W. Mallet gave 14.1932 for the sp. gr. of the solid at -38.85° , water at 4° unity; J. Dewar gave 14.382 for the sp. gr. at the temp. of liquid air, say -188° . By extrapolation from the average of 36 determinations of the sp. gr. of solid amalgams, J. P. Joule estimated the sp. gr. of solid mercury to be 15.19. A. W. Warrington gave for the vol., v , at a temp. θ° , not exceeding 40° , $v=v_0(1+0.0001819\theta)$. P. Chappius represented his measurements of the vol. v at θ° for temp. below 0° , by $v=v_0(1+1.815405\times 10^{-4}\theta +1.195130\times 10^{-8}\theta^2+1.00917\times 10^{-10}\theta^3-2.03862\times 10^{-8}\theta^4)$; and for temp. above 0° , $v=v_0(1+1.816904\times 10^{-4}\theta-2.951266\times 10^{-9}\theta^2+1.14562\times 10^{-10}\theta^3)$, where v_0 represents the vol. at 0° . J. Bosscha gave $v=2.000018077\theta$. J. W. Mallet gave 14.193 at its m.p.; and J. Dewar, 14.382 at the temp. of liquid air. M. Thiesen, K. Scheel, and L. Sell represent their results by

$$v=v_0\left\{1+0.018161\frac{\theta}{100}+0.000078\left(\frac{\theta}{100}\right)^2\right\}$$

Tables I and II, respectively denoting the sp. gr. and sp. vol. of mercury between -20° and 360° , are compiled from the results of M. Thiessen, K. Scheel, and L. Sell

TABLE I.—THE SPECIFIC GRAVITY OF LIQUID MERCURY BETWEEN -20° AND 360°
(SPECIFIC GRAVITY OF WATER AT 4° UNITY).

10×3	0.0776364	7774	9189	*0609	*2033	*3464	*4900			

—e.g. the sp. gr. of mercury at 250° is 12.9975. L. P. Cailletet, E. Colardeau, and A. Rivière gave for the sp. gr. of liquid mercury at high temp. (Fig. 4):

	500°	600°	800°	900°	1000°	1100°	1200°	1270°	1320°
Sp. gr.	12.5	12.15	11.6	11.15	10.55	10.0	8.85	8.25	7.8

A. C. Cousins, A. J. Hopkins, R. Lorenz, and E. Donath and J. Mayrhofer have discussed the relations between the sp. gr. and at. vol. of mercury with those of the other elements. J. N. Brönsted and G. von Hevesy observed no measurable difference in the sp. gr. of mercury of different geological and geographical origin.

The vapour density of mercury, air unity, has been measured by A. Bineau,³ who gave 6.7 (882°); J. B. A. Dumas, 6.976; E. Mitscherlich, 7.03; when the

theoretical value for the mol. wt. 200 is 6.93, and L. Troost obtained this value at 18.5°. V. Meyer obtained 1.97 ($H_2=2$) at 1500°; and 2.02 at 1731°. Concordant results were obtained by A. Scott, H. von Wartenberg, H. B. Baker, W. J. Kurbatoff, and F. B. Jewett. J. Bender gave for the vap. density, water unity (Fig. 4):

	1050°	1210°	1230°	1295°	1330°	1380°
Vapour density . . .	0.70	1.15	1.35	1.65	1.90	2.50

C. T. Heycock and F. H. Neville estimated the **molecular weight** of mercury from the f.p. of soln. in sodium, cadmium, tin, lead, and bismuth. M. N. Saha gave 0.69 Å. for the at. radius of mercury.

J. R. Rydberg⁴ gave 1.5 for the **hardness** of mercury, and J. C. Bull and E. M. Lagerwall found that a little mercury introduced as lead- or tin-amalgam can be used to modify the hardness of some alloys. The **surface tension** of mercury has been the subject of many investigations. For mercury in air, P. S. de Laplace⁵ found 44.05 mgrms. per mm.; S. D. Poisson, 44.21; F. Basforth and J. C. Adams, 34.00; P. Desains, 45.97 (20°); J. Magie, 45.82 (20°); E. Sieg, 46.44 (20°); M. Cantor, 45.89 (20°); L. Grunmach, 50 falling to 40 (18°); G. Quincke, 45.78 (20°); H. Siedentopf, 45.40 (20°); and G. Meyer obtained the extremes 43.68 and 51.5 (18°); H. Sentis, 39.23 (20°); J. Stöckle, 44.40 (17°); P. Lenard, 47.10 (20°); J. Piccard, 50.00; L. Matthiessen, 48.3 (20°); M. Smith, 53.9 (20°); and A. Kälähne, 44 (18°). R. Cenac, J. L. R. Morgan, E. Rothé, and C. T. R. Wilson have also discussed the measurement of this constant. The results are not very concordant, the observations are very sensitive to impurities on the surface of the mercury. W. D. Harkins and E. H. Grafton obtained 464 dynes in air, and 374.8 dynes in water; and S. W. J. Smith gave 447.5 dynes per cm. at 15°–17°. J. Palacios found 402 dynes per cm. for specially purified mercury in vacuo. The value for this constant with fresh surfaces of mercury is greater in some gases than in air. J. Stöckle, and G. Meyer found at 15°, 44.4 mgrms. per mm. in vacuo; 48.8 to 51.5 in air; 48.7 to 51.4 in oxygen; 49.8 to 50.5 in nitrogen; 47.9 to 56.5 in hydrogen; and 49.0 to 49.6 in carbon dioxide. J. G. Popesco examined the effect of ammonia, and of sulphur dioxide on the surface tension of mercury, and concluded that the effects are due to the adsorption of the gas by the mercury; J. Palacios and E. Lasala found no difference between the effect in oxygen and in vacuo. The surface tension of mercury in gases decreases with time until it approximates to the value it has in vacuo. This change is not due to the formation of a film derived from the vapour of a fat, but rather to the condensation of gas on the surface of the metal. The best representative value for mercury sat. with air lies between 44 and 46 mgrms. per mm. A. M. Worthington found the surface tension between mercury and water to be 377 dynes per cm.; G. Quincke and M. Lenkewitz gave 370. A. H. Bucherer found the surface tension of mercury is decreased in a soln. of a mercuric salt. G. Quincke, F. R. Watson, M. Lenkewitz, G. Meyer, L. Grunmach, F. Paschen, A. Gouy, H. Pellat, A. Berget, O. Wiedeburg, A. König, S. W. J. Smith and H. Moss, F. Krüger, H. Luggin, G. Lippmann, J. J. van Laar, G. Kucera, G. von Hevesy and R. Lorenz, W. Nernst, etc., measured the effect with a number of soln. of acids, alkalies, and salts; and also with a number of liquids. Thus, in mgrms. per mm. at 20°

Water.	Alcohol.	Benzene.	Olive oil.	Petroleum.	Amyl alcohol.	Turpentine.
37.47	37.33	33.5	31.0	26.0	25.5	23.4

The lowering of the surface tension follows the order: sulphuric acid, salicylic acid, picric acid, and neo-fuchsine, and the adsorption from the soln. increases in the same order. W. C. McC. Lewis investigated Gibb's equation for adsorption by mercury; R. W. Wood studied the damping effect of castor oil and glycerol on the surface waves of mercury. G. Jäger represented the effect of temp. on the surface tension, σ , of mercury in air by $\sigma = \sigma_0(1 - 0.00013\theta)$, where σ_0 is the value at 0°; and H. Siedentopf gave 0.000351 for the temp. coeff. M. Petrowa found no measurable difference in the curvature of a globule of liquid and of solid

mercury. T. R. Hogness gave $\sigma=467-0.043(\theta+39)-0.000386(\theta+39)^2$ for the surface tension of mercury at θ° . W. Hagemann gave $\sigma=472.1-0.148\theta-0.000344\theta^2$ dynes per cm.; and for the mol. surface energy $k=d\{T(M/D)^{1/3}\}/d\theta$.

	20°	74.5°	99°	146°	195°	252°	295°	353°
k	0.630	0.871	0.984	1.197	1.423	1.685	1.912	2.179

The association factor varies from 1.133 at 20° to 1.0 at 340°, in agreement with C. Liebenoff, who said: Liquid mercury is an alloy of monatomic and polyatomic mercury mols. in which the former predominate. For the **capillary constant**, G. Quincke gave $a^2=8.234$ per sq. mm.; L. Grunmach, 6.09 and 7.39; J. Stöckle, 6.548; and S. W. J. Smith, 6.725. W. D. Harkins and E. H. Grafton measured the adhesion of mercury with organic liquids; and T. Iredale also made observations on this subject. C. A. Reeser and R. Sissingh measured the thickness of surface films of smoke, air, and oil on mercury.

The curious electrocapillary properties of mercury—indicated in 1. 16, 3—have been the subject of many investigations,⁶ and they have been utilized by G. Lippmann⁷ and others in the construction of the so-called capillary electrometer, and of the drop-electrometer. K. Wolter measured the electric charge on droplets of mercury at press. of one to nine atm.

The reported values—by N. Kasterin, C. Maltézos, and those indicated in connection with the surface tension—for the **specific cohesion** of mercury vary from $a^2=5.8$ per sq. mm. of H. Sentis to 8.51 per sq. mm. of G. Quincke, and the best representative value approximates to 6.75. J. Stöckle gave 6.548 for a^2 against mercury vapour at 15°; G. Quincke, 8.234 against air at 77.5°; G. Meyer, 7.60 at 18° against air; 7.58 against oxygen; 7.58 against nitrogen; 7.33 against carbon dioxide; and 8.33 against hydrogen. M. L. Frankenheim and K. Sondhaus gave for the value of $a^2=4.050^2-0.00579\theta$, at θ° between 13.6° and 96.4°; and $a^2=3.9782-0.00529\theta$ between 107.9° and 116.7°. H. Siedentopf gave 0.000185 for the temp. coeff. of the specific cohesion.

T. Lohnstein, and J. E. Verschaffelt have investigated the theoretical curvature of the **mercury meniscus**. K. Scheel and W. Heuse, J. Palacios, J. E. Verschaffelt, H. Göckel, and L. W. Winkler studied the corrections necessary in allowing for the volume of the meniscus during measurements of volumes, etc. K. Scheel and W. Heuse, and J. Palacios have measured the volume of the mercury meniscus in tubes of different diameter. The results of the latter are indicated in Table III. If a substance under dil. sulphuric acid be brought on a surface of mercury, K. Schaum, and A. Thiel showed that there is a movement in consequence of the electrocapillary action—*vide infra*—and J. Bernstein found that if a crystal of potassium dichromate be in the vicinity of a globule of mercury under nitric acid, there is an irregular change of form in consequence of the oxidation of the mercury on one side and the dissolution of the oxide. S. R. Williams studied the effect of a magnetic field on the meniscus. H. von Euler and G. Zimmerlund studied the effect of the outflow of mercury into a soln. of mercuric nitrate.

E. Villari⁸ found that the velocity of flow of mercury from capillary tubes below 0.3 mm. diam., is in general inversely proportional to the length of the tube and proportional to the square of the radius. C. E. Fawsitt stated that the **viscosity** of mercury is nearly twice as great as that of water. G. D. West investigated the motion of a thread of mercury in a glass tube. E. Warburg found that at 17.2°, the viscosity coeff., η , is 0.016021 grm. per cm. per sec.; T. S. Schmidt, 0.01543 at 17.1°; A. Umani, 0.01577 at 10°; E. von Schweidler, 0.01684 at 0°, 0.01609 at 13.5°, 0.01589 at 20°, and 0.01483 at 40°. S. Koch gave:

	-21.4°	0°	10.1°	16.7°	99°	196.7°	282°	340.1°
η	0.01868	0.01688	0.01620	0.01575	0.01227	0.01018	0.009499	0.008975

and he represented his observations by $\eta=0.016969-0.0_4660525\theta+0.0_620847\theta^2-0.0_92455\theta^3$. K. F. Slotte gave $\eta(1+0.00366\theta)=0.01693$; and A. Batschinsky, $\eta T=\text{constant}$, where T is the absolute temp. M. Plüss, and J. E. P. Wagstaff also measured the viscosity of mercury. According to E. C. Bingham and J. P. Harrison,

the **fluidity**, *i.e.* the reciprocal of the viscosity, is a linear function of the temp. S. Koch gave $\eta=0\cdot000622$ for the viscosity of mercury vapour at 370° ; $0\cdot000162$ at 0° ; and at θ° he obtained $\eta=0\cdot000067+0\cdot00000155\theta$, between 270° and 380° . These numbers were confirmed by A. A. Noyes and H. M. Goodwin, and H. B. Phillips, and used by O. E. Meyer to calculate the molecular speed and collision frequency of the molecules. M. Knudsen, and S. Weber regard S. Koch's values for the viscosity of mercury as inaccurate. W. C. McC. Lewis gives 12,645 atm. for the **internal pressure** of mercury at 0° . The coeff. of **diffusion** of a number of metals in mercury has been measured. M. von Wogau found for lithium, $k=0\cdot66$ ($8\cdot2^\circ$) per sq. cm. per day; sodium, $0\cdot64$ ($9\cdot6^\circ$); potassium, $0\cdot53$ ($10\cdot5^\circ$); rubidium, $0\cdot46$ ($7\cdot3^\circ$); caesium, $0\cdot45$ ($7\cdot3^\circ$); calcium, $0\cdot54$ ($10\cdot2^\circ$); strontium, $0\cdot47$ ($9\cdot4^\circ$); barium, $0\cdot52$ ($7\cdot8^\circ$); thallium, $0\cdot87$ ($11\cdot5^\circ$); tin, $1\cdot53$ ($10\cdot7^\circ$); lead, $1\cdot50$ ($9\cdot4^\circ$) and $1\cdot92$ ($99\cdot2^\circ$)—G. Meyer gave $1\cdot37$ ($15\cdot6^\circ$)—zinc, $2\cdot18$ ($11\cdot5^\circ$) and $2\cdot90$ ($99\cdot2^\circ$)—

TABLE III.—VOLUMES OF MERCURY MENISCUSES IN CUB. MM.

Height in mm.	Radius of tube in mm.

1.8	90.1	137.0	193.0	259.0	336.0	424.0	526.0
1.9	—	—	205.0	275.0	356.0	449.0	557.0
2.0	—	—	217.0	291.0	377.0	474.0	589.0
2.1	—	—	—	307.0	397.0	500.0	621.0

G. Meyer gave $2\cdot09$ (15°)—cadmium, $1\cdot45$ ($8\cdot7^\circ$) and $2\cdot96$ ($99\cdot1^\circ$)—G. Meyer gave $1\cdot56$ (15°)—W. C. Roberts-Austen gave for gold, $0\cdot72$ (11°).

S. Koch gave 17,000 cms. per sec. for the **molecular velocity** of mercury vapour at 0° ; 344×10^{-8} and 1640×10^{-8} cms. for the **mean free path** respectively at 0° and 300° and atm. press.; and for the **size of the molecules** 67,200 and 14,130 sq. cms. for the total sectional area of all the molecules in 1 c.c. of gas respectively at 0° and 300° and atm. press. K. F. Slotte calculated the edge of the molecular cube of liquid and solid mercury to be $7\cdot3\times10^{-9}$ cms. H. S. Hatfield estimated that the radius of an atom is not greater than $1\cdot9\times10^{-6}$ cms.; S. Koch, that it is equal to or less than $0\cdot19\times10^{-6}$ mm. at 0° ; and J. Bernstein, from capillary phenomena, assumed the diameter of the mol. to be $6\cdot18\times10^{-7}$ mm. A. Henry calculated a **molecular diameter** $3\cdot48\times10^{-8}$ cms. and J. Perrin, $3\cdot46\times10^{-8}$ cms. W. Vaubel has made an estimate of the number of atoms in unit vol. A. A. Noyes and H. M. Goodwin say that the mean diameter of the mol. is nearly the same as that of the carbon dioxide mol., and 2.5 times as great as that of the hydrogen molecule. A. Henry calculated $66\cdot6\times10^{22}$ for **Avogadro's number**; J. Perrin, $67\cdot8\times10^{22}$; and H. Zangger, $62\cdot5\times10^{22}$ —in the latter case the values ranged

from $5.2-8.7 \times 10^{23}$. R. C. Dearle, M. Volmer, and A. Terenin made some inferences as to the structure of the atom of mercury. W. R. Fielding said that mercury at its m.p. is more polymerized in the liquid than in the solid state. F. Skaupy found an appreciable dissociation into ions and electrons by metals dissolved in mercury.

J. Dewar⁹ found the **breaking stress** of a cast mercury rod 0.2 in. diam. at -182° is 31 lbs.—about half the value for lead at ordinary temp. A. Braun found that solid mercury can be hammered and rolled, and that it is more **ductile** than gold and lead. The **tensile strength** of mercury is the greatest stress per unit area which a column of mercury can support without rupture; thus, if the mercury column is ruptured when it is h cm. longer than the height of the mercury barometer, the tensile strength $= h \times 13.65 \times 981$ dynes per sq. cm.—*vide* 1. 9, 3. The **compressibility** of mercury is smaller than that of any other liquid which has yet been measured. T. W. Richards¹⁰ and co-workers found the coeff. of compressibility, β , between 100 and 500 megabars press., to be 0.00000395 at 20° ; P. W. Bridgman found 3.79×10^{-6} kgrms. per sq. cm.; W. C. McC. Lewis, 1.30×10^{-6} at 20° ; H. V. Regnault found 3.517×10^{-6} ; M. Amaury and C. Descamps, 1.87×10^{-6} ; E. H. Amagat, 3.92×10^{-6} ; D. Colladon and C. Sturm, 3.4×10^{-6} ; G. de Metz, 3.74×10^{-6} ; L. Grassi, 2.95×10^{-6} ; P. G. Tait, 3.6×10^{-6} ; C. E. Guillaume, 3.9×10^{-6} ; M. Langlois, 1.894×10^{-6} ; and G. Aimé, 3.9×10^{-6} kgrms. per sq. cm. E. Madelung and R. Fuchs gave $3.860 \times 10^{-2} \pm 0.004$ dynes per sq. cm. Much of this work is inaccurate; J. C. Jamin's results were 50 per cent. too low. In all cases the range of press. was comparatively small. E. H. Amagat, and P. Carnazzi worked up to 3000 atm. L. Troost found that the compressibility of the vapour at about 440° , is very near that of air. P. Carnazzi found that the coeff. of compressibility of mercury at 23° is 3.7×10^{-6} , and that the coeff. increases as the temp. rises, and for any given temp. diminishes as the press. increases. F. Dolezalek and F. Speidel found for the coeff. $\beta \times 10^6$ at different temp. per atm.:

θ	0°	100°	200°	300°	400°	500°
$\beta \times 10^6$	3.70	4.17	4.64	5.11	5.58	6.05

and at 24.6° and different press. p , per sq. cm.:

p	92	264	409	532	652
$\beta \times 10^6$	4.00	3.97	3.94	3.91	3.01

showing that the dependence of the coeff. on press. is very small. P. W. Bridgman found that at 22° , the changes in vol. δv for press. p up to 12,000 kgrms. per sq. cm. were fairly closely followed by the formula $\delta v = ap + bp^2$, where the constants a and b are obtained from $\log a = 4.5911 - 10$; and $\log (-b) = 9.7782 - 10$. He gives the results indicated in Table IV and Fig. 2, for the vol. of mercury at different temp. and press. The effects are nearly constant over the entire range of press.; neither the compressibility nor the dilation changes markedly; and the lines bounding the liquid and solid states are nearly parallel. Consequently, any reversal of the ordinary effects and the appearance of any critical points are outside the range of the diagram. The results resemble those obtained with other compressible liquids. The compressibility and dilation both decrease with rising press.; and, as usual, the effect of rising temp. is to increase the compressibility.

FIG. 2.—Isothermals of Liquid and Solid Mercury.

The **thermal expansion** of mercury was measured by G. D. Fahrenheit ¹¹ in 1672; and by A. L. Lavoisier and P. S. de Laplace in 1781. The former obtained 1·0161 for the volume occupied at 100° by unit vol. of mercury at 0°; and the latter obtained 1·0175. These numbers make the coeff. of thermal expansion respectively 0·000161 and 0·000175. In 1818, P.-L. Dulong and A. T. Petit obtained 0·0001802 for the coeff. between 0° and 100°; 0·0001843 between 0° and 200°; and 0·0001887 between 0° and 300°. Since then many observations have been made because an accurate determination of this constant is of importance in the many applications of mercury, and more particularly in thermometry, barometry, etc. In 1847, H. V. Regnault repeated P. L. Dulong and A. T. Petit's work, and obtained the coeff. 0·0001815 between 0° and 100°; 0·0001840 between 0° and 200°; and 0·0001866 between 0° and 300°. He represented the coeff. of cubical expansion, α , at θ° between 0° and 300°, by $\alpha = 0\cdot00017905 + 0\cdot0000000504\theta$. J. Bosscha made a critical study of H. V. Regnault's observations. H. Militzer's value $\alpha = 0\cdot000174$ between 1·5° and 22° is too low. A. Wüllner represented

TABLE IV.—THE VOLUME OF MERCURY AT DIFFERENT TEMPERATURES AND PRESSURES.

Pressures in kgrms. per sq. cm.	Volumes in c.c. (vol. of mercury at 0° and 1 atm. = unity).

his results by $\alpha = 0\cdot0_3181163 + 0\cdot0_711554\theta + 0\cdot0_{10}21187\theta^2$; G. Recknagel, by $\alpha = 0\cdot0_318018 + 0\cdot0_894\theta + 0\cdot0_{10}5\theta^2$; and H. L. Callendar and H. Moss, their results by $\alpha \times 10^{10} = 1805553 + 12444(\theta/100) + 2539(\theta/100)^2$ —for less exact work, the latter used the linear equation $\alpha = 0\cdot00018006 + 0\cdot00000002\theta$, and W. E. Ayerton and J. Perry showed that between -39° and 0°, α varies linearly with temp., and M. Thiesen and K. Scheel gave $\alpha \times 10^9 = (181792 + 0\cdot175\theta + 0\cdot035116\theta^2)$. Measurements have also been made by P. de Heen, L. Levy, A. Mahlike, W. Herz, D. I. Mendeléeff, and G. Leonhardt. G. Vicentini and D. Omodei found for the expansion coeff. of the solid metal 0·000179; L. Grunmach gave 0·000123; and J. Dewar gave 0·0000887 for the mean coeff. of cubical expansion between -188° and 17°. H. L. Callendar and H. Moss represented the vol. v , at θ° , by $v = v_0\{1 + 0\cdot00002385\theta + 0\cdot0000000131(\theta - 100)^2\theta\}$; and M. Thiesen, by $v = v_0(1 + 0\cdot0_318182\theta + 0\cdot0_878\theta^2)$ —*vide* sp. gr. K. Scheel and W. Heuse, and N. Eumorfopoulos claimed that the results by H. L. Callendar

and H. Moss are a little low. M. Thiesen and K. Scheel's values for the mean coeff. of thermal expansion of mercury between 0° and 360° are indicated in Table V.

TABLE V.—MEAN COEFFICIENT OF THERMAL EXPANSION OF MERCURY BETWEEN 0° AND 360° .

20	18323	18338	18353	18369	18396	18403	18421	18440	18469	18480
30	18500	18522	18544	18567	18591	18616	18641	—	—	—

P. W. Bridgman found that the compressibility decreases more rapidly the higher the temp. as shown in Table III; P. Carnazzi's measurements on the effect of press. between 1 and 3000 atm., and temp. between 52.8° and 191.8° , on the coeff. of expansion of mercury, are indicated in Table VI. F. Hoffmann and W. Meissner

TABLE VI.—EFFECT OF PRESSURE AND TEMPERATURE ON THE COEFFICIENT OF THERMAL EXPANSION.

Press. atm.	52.8°	101°	150.3°	191.8°
1	0.0001809	0.0001817	0.0001827	0.0001830
1000	1769	1785	1781	1782
2000	1692	1752	1723	1732
3000	1574	1721	1651	1681

found the mean coeff. of expansion at θ° and press. p atm. between 100° and 300° to be $181.81 \times 10^{-6} + 3.47 \times 10^{-9}\theta + 3.93 \times 10^{-11}\theta^2 - 0.2 \times 10^{-15}\theta^3$; and between 200° and 500° , $\{182.22 \times 10^{-6} + 1.31 \times 10^{-9}\theta + 3.99 \times 10^{-11}\theta^2 + 9.3 \times 10^{-15}\theta^3\} \{1 - 4.7 \times 10^{-9}(p-1) - 4.7 \times 10^{-9}(p-1)^2\}$.

The **thermal conductivity** of mercury was first measured by A. J. Angström¹² in 1864, and he found the absolute conductivity at 50° to be 0.0177 cal. per cm. per sec. per degree. R. Weber found 0.0197 at 25° ; A. Berget, 0.02015 between 0° and 100° . Measurements have also been made by A. Berget, and H. R. Nettleton. G. Gehlhoff and F. Neumeier found for the thermal conductivity L between -193° and 149.4° :

L	-193°	-78.4°	-37.2°	20.7°	-0°	27.0°	99°	149.4°
	0.116	0.0776	0.0218	0.0233	0.0248	0.0276	0.0349	0.0385

The results are plotted in Fig. 3. A. W. Porter and F. Simeon found the ratio of the thermal conductivity of mercury in the solid state to that in the liquid state is 3.91. Since the electrical conductivity of mercury decreases with rise of temp., H. Herwig sought if this also applied to the thermal conductivity, and found that the heat conductivity remains constant between 40° and 160° , but this does not appear to be correct. H. F. Weber represented the thermal conductivity λ at θ° by $\lambda = 0.01479 + 0.000083\theta$. A. Berget obtained a negative temp. coeff. -0.001267 between 0° and 100° , and -0.00045 between 0° and 300° , in accord with G. Wiedemann and R. Franz's rule. A. Hirschi found indications of a change in the thermal conductivity when an electric current is

passing through mercury. A. Schleiermacher reported the thermal conductivity of mercury vapour at 203° to be 0.00001846, and to be independent of variations of press. of 3 to 10 mm., and the temp. coeff. is 0.0074.

FIG. 3.—Thermal Conductivity of Mercury
—Solid and Liquid.

by $c=0.03336-0.0000069\theta$. O. Petterson found $c=0.033266-0.0000092\theta$; and A. Naccari, found $c=0.033277-0.0000053432(\theta-17)+0.00000001667(\theta-17)^2$ between 12° and 228°. H. T. Barnes and H. L. Cooke obtained $c=0.033458-0.00001074\theta+0.0000000385\theta^2$ between 3° and 84°. The mean values of A. Winkelmann's, A. Naccari's, and J. Milthaler's determinations are :

	0°	20°	40°	60°	80°	100°	140°	180°	200°
c	0.03333	0.03319	0.03304	0.03290	0.03276	0.03262	0.03233	0.03203	0.03189

A. Naccari obtained 0.03235 at 200°, 0.03226 at 220°, and 0.03217 at 240°. W. J. Kurbatoff found the mean sp. ht. between 0° and 306° to be 0.0325 to 0.0331, which is much smaller than the result—0.03731—which he obtained six years earlier. H. T. Barnes and H. L. Cooke's value for C_p at 0° is 0.03346 gram-cal. per gram, or 0.4549 gram-cal. per c.c. F. Simon gave $C_p=2.252$ at 18.7° K., and 6.863 at 231.8° K.

The ratio of the sp. ht. of liquid mercury at θ to that at 0° shows the same results another way. The mean values of A. Bartoli and E. Stracciati's, A. Winkelmann's, and H. T. Barnes and H. L. Cooke's observations are :

C_{20}/C_0	C_{30}/C_0	C_{40}/C_0	C_{60}/C_0	C_{80}/C_0
0.9957	0.9933	0.9903	0.9863	0.9826

F. Koref obtained 0.0334 for the sp. ht. of liquid mercury between -35.6° and 3.4°. H. V. Regnault found the sp. ht. of solid mercury between -78° and -40° to be 0.03192; and therefore, like other substances, the sp. ht. of mercury is greater in the liquid than in the solid state :

	Water.	Lead.	Mercury.	Sulphur.	Calcium chloride (hydrated).
Solid .	0.502	0.0314	0.03192	0.2026	0.345
Liquid .	1.000	0.0402	0.03330	0.2340	0.555

P. Nordmeyer and A. L. Bernoulli found 0.0324 for the sp. ht. of mercury between -185° and 20°; F. Koref, 0.0329 between -77.2° and -41.8°; H. Barschall, 0.0320 between -183.3° and -71°; J. Dewar, 0.0232 at -223°; and F. Pollitzer found for the sp. ht., c , and for the atomic heat :

	-211.5°	-204°	-183°	-64°	-40°	-37°	-30°
c	0.02670	0.02715	0.028275	0.03260	0.03475	0.03490*	0.03545*
At. ht.	5.340	5.430	5.695	6.520	6.950	6.98*	7.09*

The numbers with the asterisk refer to liquid mercury, the others to the solid. Other observations have been made by M. Langlois, F. Weber, J. N. Brönsted, A. S. Russell, and C. Cantoni. According to A. Eucken, the at. ht. for liquid mercury at 0° is $C_v=5.9$, and $C_p=6.7$; at 160°, $C_p=6.59$; and at 260°, $C_p=6.63$; for solid mercury at -40°, $C_v=5.95$, and $C_p=6.7$. Above the m.p. the sp. ht. of mercury has thus a negative temp. coeff. as H. T. Barnes has shown. E. Heilborn deduced for an element with monatomic molecules the relation between the sp. ht. and temp., the expression $c=c_0v^{-1}$, where v denotes the sp. vol. which can be calculated for liquid mercury from J. Bosscha's formula, or the observed values can be used; and $c_0=0.033412$, the sp. ht. at 0°. The agreement between the observed and calculated values is satisfactory. L. Sohncke applied E. Heilborn's formula to other metals. P. W. Bridgman calculated values for the difference of the two sp. ht. of mercury, C_p-C_v , from (27), 2. 13, 1—and made observations on the influence of press. on the vol. of mercury; and he likewise calculated the influence of pressure on the sp. ht. of mercury from the thermodynamic relation $(dC_p/dp)_v = -T(d^2v/dT^2)_p$; with C_p expressed in ergs per c.c., and p in dynes, $(dC_p/dp)_v = -0.00000655$; and with C_p in gram-cals. and p in kgrms. per c.c., -0.000000154 . This variation is small, and corresponds with about $\frac{1}{2}$ per cent. for 7000 kgrms. Expressing the press., p , in kgrms. per c.c., and the sp. ht. in gram-cals. for initially unit vol. (13.596 grms.), the values of C_p and C_v at 0° are:

p	.	.	0	1000	2000	3000	4000	5000	6000	7000
C_p	.	.	0.4549	0.4547	0.4546	0.4544	0.4543	0.4541	0.4540	0.4538
C_v	.	.	0.4003	0.4035	0.4056	0.4063	0.4073	0.4073	0.4077	0.4079

Hence, while C_p decreases with an increase of press., C_v increases, and the increase is more rapid than the decrease. According to F. Richarz, the sp. ht. of solid mercury is about four times as great as when the mercury is in the gaseous state. A. Kundt and E. Warburg found the sp. gr. of mercury vapour at constant vol. to be 0.1027, and at constant press. 0.0245; and the ratio of the two sp. hts. to be 1.666. R. C. Tolman gave 41.1 for the **entropy** of mercury at 25°. G. N. Lewis and co-workers found 41.51 (gas), 17.8 (liquid).

The freezing of mercury was first reported by J. A. Braun,¹⁴ in 1760, and discussed in his paper: *De admirando frigore artificiali quo mercurius seu hydrargyrus est congelatus*. H. Cavendish gave -39.38° for the **melting point** or rather the f.p.; T. Hutchins, -39.44°; H. V. Regnault, -38.5°; G. G. Person, -39°; G. Quincke, -40°; J. Timmermans, -38.65°; F. Henning, -38.89°; F. G. Keyes and co-workers, -38.90°; K. Scheel, -38.89; and G. K. Burgess, -38.7°, with an uncertainty of about 0.1°. A. Marcet made some observations on this subject. W. Guertler and M. Pirani give -39.7° as the best representative value. According to G. Tammann, the m.p. is raised 0.0054° per kgrm. pressure per sq. cm. P. W. Bridgman found the f.p. of mercury under various press. p in kgrms. per sq. cm.:

p	.	.	-19.9°	-9.8°	0.00°	9.16°	12.88°	16.4°	18.45°
	.	.	3660	5590	7570	9450	10140	10910	11350

The change in volume which occurs when mercury freezes was observed by W. E. Ayrton and J. Perry. G. Vicentini and D. Omodei found there is over a five per cent. expansion when mercury changes from the solid to the liquid state, for 1 c.c. becomes 1.05098 c.c. J. W. Mallet found 3.7 per cent.; and L. Grunmach found that unit vol. of solid mercury becomes 1.050982 vols. in the liquid state so that the expansion is over 5 per cent. P. W. Bridgman measured the change in vol.— δv c.c. per gram—which occurs when mercury freezes at different press. — p kgrms. per sq. mm.:

p	.	.	-19.9°	-9.8°	0°	5.23°	9.16°	16.40°
δv	.	.	3660	5590	7570	8660	9450	10910
	.	.	0.002515	0.002492	0.002454	0.002426	0.002399	0.002348

M. L  meray has made observations on the relation of the m.p. to the coeff. of expansion; and H. Ramage compared the m.p. of mercury with that of other elements. M. Faraday¹⁵ showed vapour arises from mercury both in vacuo and in spaces filled with air, as shown by the "silvering" of gold-leaf kept for two months confined over mercury; consequently, "at common temp., even in the presence of air, mercury is always surrounded by an atm. of the same substance." C. W. Easley, J. W. Mallet, W. T. Burgess, E. Bindschedler, J. Davy, and M. Berthelot noted the **volatilization of mercury** at ordinary temp. by the formation of mercuric iodide about the necks of bottles containing iodine and situated some yards away from the mercury. C. J. B. Karsten found that a photographic plate, held over mercury below 0  , is affected by the vapour of that element. C. Brame claimed that the finely divided *uricules de soufre*, obtained when sulphur is condensed from the vapour, furnish a more delicate test for mercury vapour than gold-leaf. He thus showed that at 12  , mercury vapour rises above a metre, and even at 8  , it has no limited atm.; and at ordinary temp., mercury vapour rises from amalgams and mercurial ointments.

According to W. Burnett, some mercury, forming part of the cargo of a ship on the Spanish coast, ran out of the bladders which had become rotten, and found its way into the hold, where it mixed with the bilge-water. As a result, every piece of metal in the vessel was coated with mercury, and the whole ship's company was affected with violent symptoms of salivation.

G. G. Stokes, and C. Brame made observations on the diffusion of mercury vapour; the latter found that in the presence of sulphur vapour and air, mercury vapour diffuses in accord with the same law as other gases, but in the presence of iodine vapour and air, and of the mercuric iodide vapour thereby produced, the law of diffusion appears to be different. W. F. Reid observed the volatilization of mercury exposed to the sunlight, and H. V. Regnault noted the volatilization of mercury at -13  . A. Merget found that the volatilization is not arrested by freezing the mercury, and he noticed that it occurred at -44  ; and C. J. Hansen noted the metal volatilized in vacuo at -40  . R. F. Howard suggested that fine globules of mercury are more volatile than a large bead of the same element—1. 10, 1. F. Glaser measured the loss which occurs with electrolytic mercury per sq. cm. of surface per hour, and found 0.002 mgrm. was lost at room temp., 0.010 mgrm. in a desiccator over sulphuric acid; and 0.016 to 0.727 mgrm. as the temp. rose from 30   to 100  . V. Borelli observed a loss when mercury is confined in a desiccator over sulphuric acid, but not over potassium hydroxide. J. D. van der Plaats observed the volatilization of mercury confined in an atm. of carbon dioxide and nitrogen. K. Bennewitz measured the **rate of evaporation** of mercury in vacuo. The subject was also studied by M. Volmer and I. Estermann between 59   and -180  . E. Rie computed that mercury droplets of radius 10⁻⁵ cm. can distil into the larger drops. C. Barfoed noted that mercury can evaporate at ordinary temp. through a layer of water. J. W. Mallet, M. T. Lecco, and S. Hada found mercury distils over with water, and collects in the receiver. F. W. Dafert found the volatilization of mercury is prevented by covering it with glycerol, but not by water or by mineral oil. C. Barreswil stated that the presence of a little platinum accelerates the volatilization of mercury. R. W. Wood found that mercury condensed as a continuous film on glass cooled to -150  , but not at -130  , so that the critical temp. has some intermediate value.

Numerous observations have been made on the **vapour pressure, *p***, of mercury; and the results are not always concordant. Very few seem to have regarded the degree of purity of the mercury as a factor of any particular importance. M. Knudsen found:

	0��	7.1��	19.6��	30.2��	39.8��	46.2��	50.8��
<i>p</i> (mm.)	0.0001846	0.0003677	0.001138	0.002806	0.005966	0.009599	0.01331

H. Hertz found:

	60°	80°	100°	120°	140°	160°	180°	200°
p (mm.) . . .	0.026	0.093	0.285	0.779	1.93	4.38	9.23	18.25

S. Young found the following values of p , and A. Smith and A. W. C. Menzies the values of p' :

	128°	150°	200°	300°	350°	400°	450°	480°
p (cm.) . . .	—	—	1.681	24.86	67.25	154.85	315.05	459.6
p' (cm.) . . .	0.0829	0.0802	—	24.585	66.977	156.61	324.50	—

L. P. Cailletet, E. Colardeau, and A. Rivière gave:

	450°	500°	550°	600°	650°	700°	750°	880°
p (atm.) . . .	4.25	8.0	13.8	22.3	34.0	40.0	72.0	162.0

Measurements have been made by T. E. Thorpe between 2.1° and 19.9°; by E. Hagen between 0° and 100°; by O. Ruff and B. Bergdahl between 205° and 357°; by H. V. Regnault between 0° and 520°—but C. Barfoed said that these results are too high; by H. Hertz between 0° and 220°—and discussed by C. von Rechenberg; by W. Ramsay and S. Young between 40° and 520°; by T. H. Laby between 255° and 450°; by E. W. Morley between 16° and 60°; by L. Pfaundler between 15° and 98.8°; by F. B. Jewett between 140° and 300°; by L. A. Gebhardt between 130° and 310°; and by A. Villiers between 60° and 100° in atm. of hydrogen and of carbon dioxide. J. Juhlin, Lord Rayleigh, F. A. Henglein, C. F. Hill, J. Dewar, H. McLeod, P. de Heen, and T. Ihmori, have also made observations on this subject. J. D. van der Plaats found the vap. press. of mercury in carbon dioxide at 0° is 0.0047 mm.; at 10°, 0.008 mm.; and at 20°, 0.013 mm. A. Smith and A. W. C. Menzies worked between 253.97° and 434.71°, and they calculated a table for every 2° for the vap. press. of mercury between 0° and 450° from the formula: $\log p = 9.9073436 - 3276.628\theta^{-1} - 0.6519904 \log \theta$, which represents the observed results very satisfactorily between 120° and 453°. H. V. Regnault represented the vap. press. p mm. of mercury at θ ° by $\log p = 0.6640459 - 7.7449870a^{\theta} + 0.3819711b^{\theta}$; C. Antoine, by $\log p = 4.2520(2.0323 - 1000/t)$, where $t = \theta + 380$; F. A. Henglein, by $\log p = 7.5030 - 1295.9/T^{-1.0605}$ mm.; and A. Jaromlek, by $\theta = 175 + 190.5p^{0.25} - 8p^{-1}$. T. H. Laby represented his results between 15° and 270° by $\log_{10} p = 15.24431 - 3622.932T^{-1} - 2.367233 \log_{10} T$, and between 270° and 450° by $\log_{10} p = 10.04087 - 3271.245T^{-1} - 0.7020537 \log_{10} T$; M. Knudsen found $\log_{10} p = 10.5724 - 3342.26T^{-1} - 0.847_{10}T$ to be very exact near 50°, but less satisfactory at higher temp.; and A. C. Egerton gave $p = 3.72 \times 10^{13} T_{12} e^{-160 \times 10^4 / RT}$ dynes per sq. cm.

The **boiling point** of mercury was stated to be 346.5° by J. Crichton; 349°, by J. Dalton; 339°–359°, by T. Carnelley and W. C. Williams; 350°, by R. Pictet, P. H. van der Weyde, and by L. Troost; 355°, by V. Meyer and J. M. Crafts; 357°, by O. Ruff and B. Bergdahl; 356.25°, by P. Heinrich; 356.7°, by H. L. Callendar; 357.25°, by H. V. Regnault; 357.3°, by J. M. Crafts; 357.65°, by E. H. Griffiths; 356.76°, by H. L. Callendar and E. H. Griffiths; 356.95°, by A. Smith and A. W. C. Menzies (sulphur b.p. = 445°); 360°, by P. L. Dulong and A. T. Petit, and H. St. C. Deville; 357° at 760 mm., and 310° at 33 mm. press., by P. de Heen; 365° at 760 mm. and 155° in vacuo, by C. J. Hausen. F. Krafft and P. Lehmann found mercury to boil in the cathode vacuum at 174° when the press. was 195 mm. H. V. Regnault calculated the b.p. of mercury to be:

	720	730	740	750	760	770	780
p (mm.) . . .	720	730	740	750	760	770	780
B.p.	354.3°	355.0°	355.8°	356.5°	357.25°	358.0°	358.8°

The best representative value is 357.01° when the b.p. of sulphur 445° is taken as the standard of reference. According to H. C. Dickinson, to prevent the boiling of mercury in a thermometer, the space above it should be filled with some dry, inert gas, such as nitrogen or carbon dioxide, having a press. of one atm. at 300°, 4.5 atm. at 450°, and 20 atm. at 550°. L. H. Borgström gave 790° for the b.p. of mercury at 93 atm. press.

S. Weber gave 5.0 for the critical density. A. W. C. Menzies found that the liquid phase vanishes in a sealed quartz glass tube at about 1275° when the vap. press. of the mercury is about 675 atm. (the press. of the air in tube was 0.03 mm.). J. Bender and J. Königsberger determined the sp. gr. of liquid mercury and the density of its sat. vapour at different temp. The corresponding curve is shown in Fig. 4, where the critical temp. is near to 1430°, or 1703° K.; the critical press. is 1042 atm., and the critical density 5.0. These numbers were shown by S. Weber to be in agreement with R. Eötvös' rule, J. D. van der Waals' equation, and F. Trouton's constant calculated by I. W. Cederberg's formula:

$$\frac{\lambda M}{T} \left(1 - \frac{T}{T_c} \right) = 4.57 \left(1 - \frac{1}{p_c} \right) \log p_c$$

with W. J. Kurbatoff's value for the latent heat $\lambda = 67.8^\circ$ K. M. Prud'homme, and E. van Aubel discussed the relation between the critical temp., the b.p., and the m.p. of mercury.

According to G. G. Person,¹⁶ the **heat of fusion** of mercury is 600 cal. per gram-atom, or 2.84 cal. per gram at the m.p.; F. Pollitzer gave 554.5 cal. per gram-atom or 2.75 cal. per gram at -38.7° ; F. Koref gave 571 cal. per gram-atom, or 2.855 cal. per gram; and M. Langlois gave 2.836 cal. per gram. A. C. Egerton calculated the mol. ht. of fusion of mercury to be 5.6×10^2 cal. at the m.p. P. W. Bridgman calculates for the change of latent heat on freezing mercury:

	-40°	-30°	-20°	-10°	0°	10°	20°	
v	0.002535	0.002526	0.002515	0.002492	0.002454	0.002393	0.002311	c.c. per grm.
$dp/d\theta$	196400	196500	196600	196900	197600	198350	0.199300	grm. per sq. cm.
Latent heat	2.720	2.828	2.939	3.025	3.103	3.149	3.163	cal. per grm.

and for the change in the internal energy of mercury in passing from the liquid to the solid state:

	-28.66°	-18.48°	-8.31°	1.87°	12.06°	22.24°	
p	2000	4002	6005	8018	100034	12064	kgms. per sq. cm.
Work, $p\delta v$	0.118	0.235	0.350	0.459	0.557	0.649	gram-cal.
Energy change	2.732	2.717	2.693	2.657	2.599	2.516	cal. per grm.
Latent heat	2.848	2.951	3.041	3.114	3.154	3.165	

The **heat of vaporization** at 623° was found by G. G. Person to be 62 cal. per

gram or 12.4 cal. per gram-atom; W. J. Kurbatoff gave 67.8 cal. per gram, or 13.6 cal. per gram; M. Knudsen, 71 cal. per gram; M. Langlois, 77 cal. per gram; C. Musceleanu, 63.66 cal. per gram at 2×10^{-3} mm. press.; and D. Konowaloff, and J. C. G. de Marignac, 15.5 Cals. per gram-atom. W. C. McC. Lewis estimated the latent heat of vaporization at 0° to be 6.26 Cals. per gram-atom, or 31.28 cal. per gram; and at 20° , 6.34 Cals. per gram-atom, or 31.71 cal. per gram. K. K. Järvinen calculated a value from the theory of mol. attraction. A. C. Egerton gave 1.57×10^4 cal. for the **heat of sublimation** of the solid. According to W. J. Kurbatoff, **Trouton's constant** is 21.5, so that the liquid is not associated at the b.p.; C. Musceleanu found 19 to 23; and E. van Aubel, 20. R. de Forcrand found when the latent heat of vaporization is 13.945 Cals. per gram-atom, and the b.p. $T=630$ K., $\lambda/T=10.1 \log T-1.5-0.009T+0.0000026T^2$, or 22.135. P. de Heen has discussed the relations between the saturated vapour and Trouton's rule; J. P. Montgomery, the relations between several constants, and Trouton's rule; W. Vaubel gave the **heat of dissociation**, $\text{Hg}_2=2\text{Hg}-446$ Cals.; C. Cantoni, the **heat of disaggregation** of the molecules of the liquid; and C. Cantoni, and W. C. McC. Lewis, the latent **heat of expansion** of the liquid against the external press.—the latter gives 13280 atm. per sq. cm. or 316 cal. per c.c. E. Beckmann and O. Liesche gave 114.0 for the **boiling constant** of mercury. W. G. Duffield gave 9.4×10^4 to 11.5×10^4 cm. per sec. for the velocity of the mols. projected from boiling mercury. G. Bakker calculated the energy transformation between the capillary film of the liquid and the vapour. I. Langmuir has studied the consumption of electrical energy necessary to maintain the temp. of a tungsten wire in mercury vapour. O. Sackur obtained for the chemical constant $C=-2.055+1.5 \log M$, where M is the mol. wt.

The **index of refraction**, μ , of liquid mercury; and the **absorption coefficient**, k , such that the amplitude of a wave after travelling one wave-length, λ , in the metal, is reduced in the ratio $1:e^{-2\pi k}$ have been measured by W. Meier,¹⁷ who found:

λ	325.4	361.1	398.2	441.3	467.8	508.0	589.3	630.0
μ	0.679	0.774	0.921	1.011	1.149	1.312	1.624	1.719
k	3.323	3.510	3.438	3.387	3.207	2.986	2.713	2.733

E. van Aubel found $\mu=2.30$ for the H^α -line. P. Drude obtained for $\lambda=589.3$, $\mu=1.73$, and $k=2.87$. W. von Uljanin has also measured the index of refraction and absorption coeff. of liquid mercury. R. W. and R. C. Duncan found for light of wave-length 665.0, 589.3, and 472.0 the respective indices of refraction 2.34, 1.92, and 1.35; and absorption coeff. 2.47, 2.78, and 3.42. C. Cuthbertson found the refractive index of the vapour of mercury to be 1.001857, and C. Cuthbertson and E. P. Metcalfe found for the wave-lengths 656.2, 598.3, 545.9, and 518.3, the respective values 1.001799, 1.001866, 1.001882, 1.001885; and for the visible rays, $\mu-1=0.001755(1+2.265)0.001755(1+2.265\lambda^{-2}10^{-10})$. The rate of change is thus about four times as great as with air; and J. C. McLennan gave:

λ	4860	5132	6110	6230	6234.31
μ	1.000949	1.00943	1.000924	1.000882	1.000860

L. Natanson also measured the index of refraction of mercury vapour. T. des Coudres, and L. P. Wheeler measured the index of refraction of liquids—water, alcohol, hydrochloric acid, sodium thiosulphate soln., petroleum, chloroform, olive oil, turpentine, and carbon disulphide—by reflexion of light from the surface of mercury immersed in the liquid. P. Drude, and W. Meier measured the percentage **reflecting power** of mercury; the latter found for $\lambda=326$, 441, 589, and 668, the respective values 66, 74, 75, and 77 per cent. H. Rubens and E. Ladenburg measured the reflecting power for long waves; R. W. Wood, the selective reflexion of monochromatic light by mercury vapour; and P. P. Koch and W. Friedrich, and

B. O'Brien and L. P. Wheeler, the anomalous **dispersion** of mercury vapour. R. W. Wood, and A. von Malinowsky studied the resonance radiation of mercury vapour; the former found that mercury vapour reflects light of wave-length 2536 in much the same way as would a coating of silver inside the bulb. S. Procopiu found the birefringence of toluene is positive, but negative when mercury is shaken therewith. Similarly with benzene, etc. R. W. Wood studied the selective reflection, and the polarized **resonance radiation** of mercury vapour, and Lord Rayleigh, the polarization of light scattered by mercury vapour. M. Tiffeneau and C. Sommaire gave 12·848 for the **atomic refraction** of mercury.

W. N. Hartley,¹⁸ and R. W. Wood observed that a bluish-green **fluorescence** appears when sparks from zinc or cadmium, or cadmium-lead electrodes passed through mercury vapour; the fluorescence gradually decreases in intensity with rise of temp., and finally vanishes altogether, and the phenomenon recurs in the reverse order as the vapour is cooled. E. Paterno and A. Mazzucchelli obtained no fluorescence at 1500° in a quartz tube. J. Franck and R. W. Wood observed that the phenomenon is sensitive to the presence of electronegative gases—oxygen eq. to 3 mm. press. prevents the fluorescence; helium has no appreciable influence. J. N. Collie found all gases luminesce when shaken with mercury. The phenomenon has been studied by W. Steubing, W. Wein, J. H. Vincent, J. S. van der Lingen, W. Matthies, J. Königsberger, A. Perot and J. Bosler, A. Pflüger, R. Pohl, A. Klages, G. C. Schmidt, J. von Kowalsky, F. W. Aston, B. Reismann, F. S. Phillips, Y. T. Yao, G. Cario, etc. O. Wolff found no fluorescence in ultra-violet light. The luminosity which occurs in many gases when an electric discharge is passed through the gas, and persists for some time after the discharge has ceased, has been traced to the readjustment of chemical equilibrium upset by the discharge—oxygen, and nitrogen. N. H. Ricker attributed the phenomenon with mercury vapour to the recombination of positive and negative ions to form neutral mols. N. H. Ricker studied the after-glow or **luminescence** of mercury vapour distilled from an arc in vacuo. The luminescence is attributed to the recombination of the positive and negative ions produced by the discharge as suggested by C. D. Child. The last-named obtained a continuous spectrum with mercury between 120° and 400°, and at a low current density. J. S. van der Lingen studied the fluorescence of mercury vapour excited by X-rays.

The action of **radium radiations** on mercury have been studied by G. le Bon, A. S. Russell, T. S. Taylor, K. Siegl, H. Greinacher, etc. J. Stark and co-workers studied the action of the **cathode rays** on mercury; and S. Landau and H. Piwnikiewicz, the action of **X-rays**. A. Müller studied the high frequency or **X-ray** spectrum of mercury. In general, the fluorescence increases with increasing vapour density; the temp. has no influence on the intensity of the glow; but the glow is diminished when foreign gases are present; and the spectrum is continuous. M. de Broglie, and W. Duane and co-workers studied the critical absorption of X-rays of wave-lengths $\lambda \times 10^8$ cms. by mercury, and found respectively 0·146, 0·1479, and 0·1491. H. J. C. Ireton attempted to find if mercury atoms emit radiations of wave-length 5460·97 and 4046·78 Å. when they have been made to absorb light of wave-length 2536·72 and 4358·66 Å., and found evidence to support the hypothesis. The phosphorescence caused by **canal rays** was investigated by J. Königsberger and J. Kutschewsky, W. Wien, A. Rüttenauer, J. Stark, etc. R. de J. F. Struthers and J. E. Marsh found purified mercury had no action whatever on a gelatine dry plate; N. Piltschikoff found no sign of the emission of the so-called Moser rays of mercury. W. Steubing showed that the vapour of mercury is ionized by the light from a mercury lamp. The current was 10^{-8} amps. when the press. was zero. This represented the **photo-electric effect** at the electrodes. The vap. press. of the mercury was increased by heat, and the current rose to a maximum of 6×10^{-8} amps. The current increased almost linearly with the potential difference up to 12 volts, the maximum employed. J. G. Popesco studied the relation between the surface tension and the photo-electric effect.

W. J. Russell, R. Liesegang, A. Colson, J. H. Vincent, and H. Muraoko and M. Kasuya studied the action of mercury on **photographic plates**.

It is generally stated that mercury gives no **flame spectrum**. A. Mitscherlich¹⁹ noticed that mercury cyanide, in the oxyhydrogen flame, furnished the spectral lines 546·0 and 435·8, and G. D. Liveing and J. Dewar observed the line 253·6 with mercury cyanide in the cyanogen flame, but A. Gouy observed no lines with mercuric salt soln. sprayed in Bunsen's flame; W. N. Hartley and H. Ramage observed neither lines nor bands when mercuric oxide is heated in the oxyhydrogen flame; C. de Wauville none with mercuric oxide or chloride in the oxycoal-gas or oxyhydrogen flame; G. D. Liveing and J. Dewar none during the explosion of electrolytic gas; and A. S. King none by heating mercury in the electric furnace. E. Goldstein observed no lines in the spectrum of mercury diphenyl. C. de Wauville did obtain the 253·672 line with mercuric nitrate, acetate, and cyanide. G. D. Liveing has also investigated this subject. C. Wheatstone first reported seven lines in the **spark spectrum** of mercury in air, under reduced press., or under water. D. Alter, A. Masson, A. J. Angström, J. Plücker, F. Brasack, G. Kirchhoff, T. R. Robinson, W. A. Miller, W. Huggins, R. Thalén, J. Plücker and J. W. Hittorf, W. N. Hartley, A. F. Sundell, J. S. Ames, E. Demarçay, A. Schuster and G. Hemsalech, P. G. Nutting, H. E. Watson, H. Finger, E. Castelli, G. Wendt, J. de Kowalsky, etc., made observations on this subject. The principal lines in the spark spectrum from a soln. of mercuric chloride are a feeble line of wave-length 615·2 $\mu\mu$ in the orange-yellow; a yellow double line, 53·0 and 53·7, on the scale, or 579·0 and 576·9 $\mu\mu$ — γ , Fig. 5; feeble yellowish-green lines, 567·8 and

FIG. 5.—Spark Spectrum of Mercury.

559·5 $\mu\mu$; an intense green line, 546·1 $\mu\mu$, Fig. 5—almost in the same place as one of the silver lines; a feeble blue line, 491·6 $\mu\mu$; a stronger indigo-blue line, 126·4, on the scale, or of wave-length 435·8 $\mu\mu$, Fig. 5; and two feeble violet lines, 407·8 and 404·7 $\mu\mu$. The spark spectrum of mercuric nitrate is not so intense as the spectrum from mercuric chloride; a highly exhausted vacuum tube containing mercury, or the light from an arc between the mercury electrodes of a mercury lamp, gives a similar spectrum. According to E. Cappel, the sensitiveness of the spectrum of mercury in the induction spark is half that of copper, and about $\frac{1}{10000}$ th part of mercury can be detected. If the electric discharge is passed through hot mercury vapour not far from its point of condensation, and the current density is small, a **continuous spectrum** ranging from the red to the ultra-violet, and very prominent in the green, is produced. As the current density increases the **line spectrum** becomes more and more prominent, and the continuous spectrum less so. With a condenser in circuit, the line spectrum alone is produced. C. D. Child showed that the glow at the cathode gives the line spectrum more prominently than that of the anode, and that the continuous spectrum does not depend on the kind of glass, the kind of electrodes used, nor on the purity of the mercury. The **fluorescent or resonance spectrum** of mercury vapour was studied by J. S. van der Lingen, R. W. Wood, and E. P. Metcalfe and B. Venkatesachar. J. Franck concluded that the number of rayless transformations in the collision of excited atoms, with slow-moving atoms, is not small compared with unity. The **arc spectrum** of mercury has been studied by H. Kayser and C. Runge, F. M. Walters, A. L. Hughes, H. Buisson and C. Fabry, G. Wiedemann, L. Arons, C. Fabry and A. Perot, O. Lummer, F. Exner and E. Haschek, R. Küch and T. Retschinsky, S. Procopiu, A. Pflüger, etc. C. Ramsauer and F. Wolf studied the duration of the spectral lines in an extinguished arc. S. Procopiu studied the variation in

the arc spectrum with the conditions under which it is formed. By sparking a soln. of the chloride L. de Boisbaudran obtained a **band spectrum** between 659.7 and 549.8, and between 529.2 and 522.2, but it is not known whether these belong to the metal or to the chloride. Observations on the band spectra of mercury and its compounds have been made by E. Wiedemann and C. G. Schmidt, B. O. Pierce, A. C. Jones, H. Nagaoka, E. Hulthén, A. Kratzer, G. Ciamician, H. W. Vogel, E. Gehrecke and L. C. Glaser, A. Kalähne, W. B. Huff, E. Liese, A. Hagenbach and H. Konen, J. Stark and co-workers, J. M. Eder and E. Valenta, J. Lohnmeyer, O. Lummer, etc. According to J. Lohnmeyer, the band spectra of the mercury halides are very complicated, and this the more the greater the at. wt. of the contained halogen. J. N. Lockyer found that mercury vapour gives no visible **absorption spectrum**. J. C. McLennan and W. W. Shaver photographed the spectrum of mercury vapour up to $\lambda=11137 \text{ \AA}$.; they found that non-luminous mercury vapour does not absorb radiation of $\lambda=10140 \text{ \AA}$.; but very slight deposits of mercury on the walls of the vessel may give an absorption; radiation of $\lambda=10140 \text{ \AA}$. may be strongly absorbed by luminous mercury vapour. Hence, from the absence of absorption of radiation $\lambda=10140 \text{ \AA}$. by non-luminous mercury vapour, the resonance potential of 1.26 volts does not apply to the atoms of mercury in their ordinary state, in addition to the well-established one of 4.9 volts corresponding with $\lambda=2536.72$. The selective absorption of light by electrically luminescent mercury vapour has been studied by E. P. Metcalfe and B. Venkatesachar; and A. Terenin shows the bearing of the absorption spectrum on the structure of the mercury atom. R. J. Strutt, R. W. Wood, W. N. Hartley, C. R. Crymble, T. W. Case, J. J. Dobbie and J. J. Fox, H. Ley and W. Fischer, J. Frank and W. Grotrian, R. Küch and T. Retschinsky, etc., made further observations on the absorption of light by mercury vapour. R. C. Dearle measured the infra-red radiation spectrum of mercury. J. C. McLennan, D. S. Ainslie, and F. M. Cale studied the absorption of the $\lambda=5460.97 \text{ \AA}$. by mercury vapour, F. H. Newman studied the relative visibility of the spectra of mercury and the alkali metals.

A. S. King studied the causes of the variability of the spark spectra of mercury. G. Ciamician, and P. Vaillant studied the effect of variations of *temperature* on the spectrum; G. Ciamician, J. F. Mohler, W. J. Humphreys, A. Kalähne, E. S. Ferry, J. Stark and M. Reich, M. Ritter, R. Küch and T. Retschinsky, etc., studied the effect of *pressure*; A. Kalähne, and E. S. Ferry, the effect of *current intensity*; J. Franck, the excitation potential of the mercury lines; G. M. J. McKay observed no evidence of emission lines from mercury at 3200° K .; C. Füchtbauer, the excitation of the mercury lines by *ultra-violet rays*; H. P. Waran, the effect of a *magnetic field*; G. F. Hull, M. Ritter, and J. Stark and co-workers, the effect of an *electric field* on the spectral lines; P. Zeemann, A. A. Michelson, J. C. Shedd, H. M. Reese, H. Starke and J. Herweg, M. M. Risco, H. Nagaoka and T. Takamine, F. Paschen and co-workers, Lord Blythwood and E. W. Marchant, A. Gray and A. W. Stewart, C. Runge and F. Paschen, G. Berndt, E. Gehrecke and O. von Baeyer, H. Lunelund, W. Lohmann, T. Royds, W. Voigt, H. P. Waran, A. Landé, M. Tenani, H. Nagaoka, P. P. Koch, and P. Gmelin studied the **Zeemann-effect**. A. Landé, P. Lewis, P. G. Nutting, R. W. Wood, J. N. Collie, G. Berndt, E. Wiedemann, J. Stark, G. Gehlhoff, R. J. Strutt and A. Fowler, and H. Finger studied the influence of *impurities*, and C. Füchtbauer and G. Joos, the effect of nitrogen, hydrogen, and carbon dioxide on the spectrum of mercury. A. Hagenbach, A. Dufour, M. Glagoleeff, J. Stark and co-workers, G. F. Hull, etc., have studied the **Doppler effect**.

The **ultra-violet spectrum** of mercury was examined by L. and E. Bloch, W. Hallwachs, K. Wolff, F. Paschen, A. Tian, A. L. Hughes, J. M. Eder and E. Valenta, J. Courmont and C. Nogier, G. le Bon, E. Castelli, W. N. Hartley, G. D. Liveing and J. Dewar, F. Exner and E. Haschek, H. Lehmann and R. Straubel, J. Stark and S. Kinoshita, R. W. Wood and D. V. Guthrie, etc.; the **ultra-red spectrum**, by H. Lehmann, W. J. H. Moll, F. Paschen, W. W. Coblentz

and W. C. Geer, etc.; the **canal ray** spectrum, by J. Stark and co-workers, and G. F. Hull; the **cathode ray spectrum** by P. Lewis; and the spectrum from a glowing lime cathode in mercury vapour by F. Horton. J. J. Dobbie and J. J. Fox found the vapour of mercury shows very little absorptive power for light.

The **series spectrum** of mercury is more complex than those of zinc and cadmium. A comparison is shown in Fig. 3, Cap. 29. H. Kayser and C. Runge, and C. Runge and F. Paschen represent two series of triplets by the formulæ :

FIRST SERIES.

$$\begin{aligned}\lambda^{-1}10^8 &= 40159\cdot60 - 127484n^{-2} - 1252695n^{-4} \\ \lambda^{-1}10^8 &= 44792\cdot87 - 127484n^{-2} - 1252695n^{-4} \\ \lambda^{-1}10^8 &= 46560\cdot78 - 127484n^{-2} - 1252695n^{-4}\end{aligned}$$

SECOND SERIES.

$$\begin{aligned}\lambda^{-1}10^8 &= 40217\cdot98 - 126361n^{-2} - 613268n^{-4} \\ \lambda^{-1}10^8 &= 44851\cdot01 - 126361n^{-2} - 613268n^{-4} \\ \lambda^{-1}10^8 &= 46618\cdot44 - 126361n^{-2} - 613268n^{-4}\end{aligned}$$

These formulæ account for 25 out of over 95 lines in the arc spectrum, but some strong lines are not accounted for—e.g. 253·672. Other observations on the structure of the spectrum were made by J. R. Rydberg, C. Fabry and A. Perot, O. Lummer, R. J. Strutt, J. Barnes, L. Janicki, E. Gehrcke and O. von Baeyer, P. G. Nutting, B. Galitzin, F. Bates, H. Nagaoka, H. W. Webb, F. Paschen, H. Dingle, F. Paschen and E. Back, T. Royds, F. Horton, H. Hermann, S. R. Milner, H. Lunelund, G. Ciamician, W. N. Hartley, W. Ritz, A. Pflüger, L. Grebe, J. Franck and E. Einsporn, H. Stansfield, H. Konen, J. C. McLennan, J. Stark and co-workers, R. W. Wood, W. W. Coblentz, H. Gray, F. F. S. Bryson and J. Logie. R. Seeliger studied the conditions for the excitation of the different series of lines. G. Stead and B. S. Gossling found the **ionization potential** of mercury vap. to be 10·8 volts; J. C. McLennan and J. F. T. Young gave 10·45 volts. C. G. Found gave 10·1 volts; and A. L. Hughes and A. A. Dixon, 10·2 volts. K. T. Compton gave 4·65–4·99 volts for the minimum ionization potential. E. Einsporn and G. E. Gibson and W. A. Noyes have also measured this constant. J. F. Mohler and co-workers found 10·2 volts for the ionization potential, and 4·76–6·45 volts for the **resonance potential** of mercury vapour. M. N. Saha and E. Einsporn have made observations on this subject. J. A. Eldridge studied the energy losses in the ionization and resonance of mercury vapour; he also investigated the probability of collisions between electrons in mercury vapour. H. Sponer computed the frequency of the inelastic collisions of electrons producing the resonance line 2536·7 Å. in mercury vapour. T. C. Hebb studied the effect of temp. on the **arc voltage** of mercury; Y. T. Yao, K. T. Compton, and G. Stead and E. C. Stoner, the low voltage arc in mercury vapour; and G. Dejardin, the ionization of mercury in argon which begins at a potential of 11·3 volts; he also examined the effect with helium. The resulting spectra were also investigated.

The **electrical resistance** of mercury is the standard of reference for the International Ohm, which is defined as “the resistance offered to an unvarying electric current by a column of mercury at 0°, 14·4446 ± 0·00006 grms. in mass, of a constant cross-section, one sq. mm., and of a length of 106·245 ± 0·004 cms.” Very many measurements have accordingly been made of the electrical resistance, or of the reciprocal, the **electrical conductivity**, of mercury—e.g. by A. Matthiessen and co-workers,²⁰ L. Lorenz, E. Becquerel, J. Müller, L. Grunmach, C. L. Weber, W. Siemens, L. Cailliet and E. Bouty, G. P. Grimaldi, Lord Rayleigh and H. Sidgwick, R. T. Glazebrook and T. C. Fitzpatrick, R. J. Strutt, H. Wuilleumier, L. Duncan, G. Wilkes and C. T. Hutchinson, J. V. Jones, W. Orloff, A. Berget, H. Passavant, H. J. Rink, E. von Schweidler, A. Bernini, H. Schulze, etc. The sp. resistance of mercury at 18° is $0\cdot958 \times 10^{-4}$, and the relative increase per 1° is $+0\cdot92 \times 10^{-3}$. The reciprocal of the resistance of a cm. cube of mercury at 0° is nearly $1\cdot063 \times 10^4$ reciprocal ohms. E. Dorn gave $1\cdot06285 \times 10^4$. The electrical conductivity of liquid mercury in rec. ohms. $\times 10^{-4}$ between 0° and 350°, is:

0°	10°	25°	50°	100°	150°	200°	250°	300°	350°
1·063	1·0535	1·0386	1·0148	0·9685	0·9218	0·8751	0·8290	0·7831	0·7378

showing a steady decrease in the conductivity with rise of temperature. The values

of J. Dewar and J. A. Fleming, recalculated by H. Dickson, for solid mercury are ($\times 10^{-4}$):

-36.1°	-37.0°	-38.1°	-39.2°	-40.7°	-50.3°	-102.9°	-147.5°	-183.5°
1.24	1.44	2.205	2.74	3.46	4.70	6.65	9.46	14.35

showing a rapid increase in the conductivity as the temp. falls. The conductivity of solid mercury at the m.p. is 4.087 times as great as that of the liquid metal at the same temp.

FIG. 6.—The Effect of Temperature on the Electrical Conductivity of Mercury.

to 0.086 ohm at 4.3° K., and at 3° K. to 3×10^{-6} ohms—*i.e.* one millionth part of its value at 0° or 273° K. H. K. Onnes and J. Clay give for the resistance, R ohms, of mercury at very low temp.:

	0°	-183.00°	-205.01°	-215.34°	-252.93°	-258.81°
R	97.126	7.2650	5.3900	4.5057	1.2613	0.7534

The resistance of the metals examined by H. K. Onnes becomes so extremely small as practically to vanish as the temp. approaches absolute zero. Thus supposing the resistance, R , of mercury at 0° or 273.1° K. is unity, then, at 20.1° K., $R=0.05641$; at 14.3° K., $R=0.03369$; at 4.3° K., $R=0.0021$; at 3.0° K., $R=0.00003$; and at 1.5° K., $R=0.00000$. Otherwise expressed, the resistance at 1.8° K., is barely one thousand millionth part of the value at ordinary temp., and at absolute zero, mercury will offer no measurable resistance to the passage of an electric current. H. K. Onnes calls this condition *super-conductivity*. A thread of mercury in that state will carry 1000 amps. without becoming warm, or setting up an e.m.f. at its ends. P. W. Bridgman found a discontinuity in the change of resistance with temp. just before the superconducting stage is reached; and he ascribed it to a polymorphic change of structure.

Several formulæ have been proposed to represent the relation between the temp. and the resistance of mercury. The temp. coeff. α for the resistance R at θ° in the formula $R=R_0(1+\alpha\theta)$, *i.e.* on the assumption that the resistance is proportional to the temp., is 0.0007443, according to A. Matthiessen and M. von Bose; 0.000889, E. W. von Siemens and J. G. Halske; 0.000869, Lord Rayleigh and H. Sidgwick; 0.000884, R. Lenz and N. Restzoff; 0.000895, E. Mascart, F. de Neville, and R. Benoit; and 0.000907, K. Strecker. R. T. Glazebrook gave $\alpha=0.000879$ between 0° and 15°; and K. Bornemann and G. von Rauschenplat give 0.000994 between 50° and 150°, and 0.000855 between 150° and 300°. There are, however, small deviations from the proportional law, for the temp. coeff. of the resistance increases as the temp. increases. D. Kreichgauer and W. Jäger gave $R=R_0(1+0.0008827\theta+0.00000126\theta^2)$ between 15° and 26°; C. Guillaume, $R=R_0(1+0.000881\theta+0.00000101\theta^2)$ between 0° and 60°; R. Benoit, $R=R_0(1+0.000882\theta+0.00000114\theta^2)$ between 0° and 360°; G. Vicentini and D. Omodei, $R=R_0(1+0.0008989\theta+0.06695\theta^2+0.081018\theta^3)$ between 0° and 350°; and F. E. Smith, $R=R_0(1+0.00088788\theta+0.0510564\theta^2)$ in a Jena-glass tube and $R=R_0(1+0.00088776\theta+0.0510376\theta^2)$ in a hard green-glass tube, between 0° and 22°. W. Jäger and H. von Steinwehr gave $R=R_0(1+889.15$

$\times 10^{-6}\theta + 0.99360 \times 10^{-6} \times \theta^2$) in a quartz vessel between 0° and 100° ; and they also measured the conductivity of the isotopes of mercury. A. Baltruszajtis found the resistance of liquid mercury to be $R=R_0(1+0.000882\theta+0.0692\theta^2)$; and of solid mercury $R=R_m(1+0.00456\theta)/(1-0.00456 \times 38.85)$ between the m.p. and -73° , where R_m denotes the resistance of the solid at the m.p. -38.85° . G. Wiedemann and R. Franz's ratio of the thermal conductivity, λ , and the electrical conductivity, κ , shows a small break at the m.p. as illustrated by the curve, Fig. 7. L. Lorenz's number, $\lambda/\kappa T$, is not proportional to the temp.

	-193°	-44°	-37°	-21°	0°	27°	100°	150°
$\lambda/\kappa \times 10^7$	8.4	15.5	20.6	22.1	23.7	26.9	37.0	42.5
$\lambda/\kappa T \times 10^{10}$	105	68	88	88	87	90	99	100

The effect of pressure on the resistance of mercury was found by R. Lenz to decrease about 0.02 per cent. per atm. A. Lafay found $dR/R = -0.1251$ for 4500 kgrms. per sq. cm., i.e. about 0.02 per cent. per atm. C. Barus found a press. coeff. of -0.00003 up to 400 atm.; and A. de F. Palmer, -0.0000332 up to 2000 kgrms. per sq. cm. The last-named considers that the presence of occluded air is responsible for the high coeff. 0.0002 obtained by R. Lenz. According to C. Barus, therefore, $-dR/R = 30 \times 10^{-6} dp$; but, according to L. Grassi, $-dv/v = 3 \times 10^{-6} dp$; and by division, $dR/R = 10 dv/v$. Again, $dR/R = 800 \times 10^{-6} dT$; and $dv/v = 180 \times 10^{-6} dT$; and by division, $dR/R = 4.4 dv/v$. P. W. Bridgman obtained the results indicated in Table VII for the effect of press. on the electrical resistance of mercury; and the results in Table VIII for the resistance of mercury at different press. and temp. when the resistance at atm. press. and the indicated temp. is unity. The resistances for the liquid were obtained by extrapolation beyond the f.p. It is estimated that the press. coeff. of the solid is between 0.000002 and 0.00002. The change in the resistance liquid-solid becomes less at higher press. and temp.; and the effect of press. on the resistance of the liquid is greater than it is on the

FIG. 7.—Effect of Temperature on G. Wiedemann and R. Franz's Ratio.

TABLE VII.—THE EFFECT OF PRESSURE ON THE ELECTRICAL RESISTANCE OF MERCURY.

solid. A. de F. Palmer and E. Lisell showed that the change in the electrical resistance of mercury by press. furnishes a means of measuring press., and the mercury resistance gauge was employed by P. W. Bridgman in his work on the effect of high press. on the properties of matter.

G. Berndt found that there is scarcely any change in the electrical resistance of mercury in a *magnetic field*; A. Hirschi, that the resistance of a column of mercury through which an *electric current* is flowing is greater than when no current is passing; and W. Jäger, that the resistance does not change when mercury is kept 6 years in a Jena-glass vessel—*vide supra*, F. E. Smith. W. Jäger and H. von Steinwehr measured the electrical conductivity of the different *isotopes* of mercury. If a thin triangular piece of amalgamated copper is floated on a trough of mercury, and a large direct current is passed through the bath, the piece moves across the bath blunt end foremost. E. F. Northrup explained the phenomenon as a result of the *pinch effect*, or the greater radial contraction of a conductor at the smaller than at the larger end; and C. Hering attributes the phenomenon to the tendency of the mercury conductor to stretch or lengthen itself more at one end than at the other owing to the greater density of the magnetic flux encircling the main path of the current being greater at the small end than at the larger end; and the effect is to make the lines of force act like compressed helical springs under unequal compression.

The effect of *impurities* in the mercury has also been investigated. Lord Rayleigh and H. Sidgwick found that the resistance of purified mercury is not affected by distillation in vacuo; and K. Strecker, that dissolved air does not change the resistance appreciably. R. Lenz and N. Restzoff could detect no

TABLE VIII.—THE CHANGE IN ELECTRICAL RESISTANCE WHEN MERCURY CHANGES FROM LIQUID TO SOLID AT DIFFERENT PRESSURES.

Temp. °	Press. kgrms. per sq. cm.		Resistance in terms of that at atm. press. and 0°.

difference in the conductivity of mercury in the presence and in the absence of mercuric oxide. W. Siemens found that additions of small quantities of metals—*e.g.* bismuth—which are bad conductors raise the conductivity of mercury. With the addition of a very small proportion of zinc, gold, or silver the conductivity is greater, and with the addition of a very small proportion of bismuth, lead, or tin greater than the value calculated from the volume of the mixture. A. Matthiessen has compared the observed conductivity with the result calculated from the relative vol. of mercury and the added metal. C. Michaelis stated that the conductivity of amalgams with up to 2.3 per cent. of zinc, cadmium, tin, lead, copper, silver, gold, and bismuth, is approximately the same as that calculated from the volume relations of the components. K. Bornemann and co-workers studied the effect of additions of the alkali metals.

The vapour of mercury was shown by W. Hittorf,²¹ J. J. Thomson, and G. C. Schmidt, to be a very poor conductor of electricity. The electrical resistance of mercury vapour has been measured by H. Herwig, R. J. Strutt, P. C. Hewitt, A. P. Wills, etc. According to R. J. Strutt, the resistance of sat. mercury vapour at a red heat is much greater than that of the liquid, being 4×10^{-6} against 0.25. C. Wheatstone, in 1835, studied the brilliant light emitted when mercury is vaporized in an electric arc; and likewise also when zinc, cadmium, tin, bismuth, and lead are similarly treated. Patents for mercury lamps were obtained by E. H. Jackson,

1852; by C. Binks, about 1853; by J. T. Way, 1856; by C. W. Harrison, 1857; by C. W. Siemens, 1867; by W. Prosser, 1875; and by J. Rapieff, about 1879. H. J. Dowsing and H. S. Keating, 1896, made the first true mercury lamp in which a partially evacuated tube was employed, and P. Cooper-Hewitt's lamp appeared about 1901. Since clear fused quartz was introduced into commerce, various forms of mercury lamp with transparent fused quartz have been made—e.g. H. A. Kent and H. C. Lacell's lamp, and many others. In the modern *mercury arc lamp*, a long glass—or quartz glass—vessel is more or less exhausted. The vessel contains liquid mercury at one end, and this serves as cathode; a disc of iron or nickel serves as anode at the other end of the vessel. By tilting the body of the lamp so as to make a temporary short circuit between anode and cathode, by preheating the cathode surface with a spark discharge, or by some other device, mercury vaporizes, and a mercury arc is formed. The anode remains cold and non-luminous; the cathode also is non-luminous, so that the emission of light proceeds from the column of mercury vapour which carries the current. The anode is made with a large surface to prevent it becoming unduly heated, and such lamps can be operated only on direct current since the arc is extinguished when the current is reversed—*mercury interrupters*. If, however, the mercury vapour lamp has a glowing oxide electrode, the radiation of heat enables the mercury to volatilize, and the arc can be maintained with an alternating current. A. Sellerio studied the velocity of the arc stream between mercury and carbon.

W. R. Grove found that the metals can be arranged in a series according to their faculty of forming an electric arc—K, Na, Zn, Hg, Fe, Sn, Pb, Sb, Bi, Cu, Ag, Au, Pt. The mercury arc in a quartz glass vessel is an important source of ultra-violet light. J. Pollak estimated that 25 per cent. or more of the energy radiated by the lamp is lost for the production of light, and is wasted in the condensing chamber of the lamp. The properties of the mercury arc have been studied by J. H. Vincent, A. L. Hughes, A. Dufour, W. Hoeppe, R. L. Morrison, S. R. Milner, P. A. Huguenin, K. von Natterer, F. M. Perkin, E. Darmois and M. Leblanc, C. Winther, G. Gehlhoff, E. Weintraub, M. Leblanc, M. von Recklinghausen, J. Rodet, J. Escard, R. Seeliger and G. Mierdel, etc. The electrodes have been discussed by R. de Valbreuze, L. Cassuto, H. E. Ives, O. Lehmann, J. Stark and co-workers, E. Urbain, C. Scal and A. Feige, etc. General reviews have been made by R. B. Hussey, M. Leblanc, etc.

Up to a certain current value of about 6.5 amps.—dependent on the geometrical shape of the lamp, and its external temp.—the arc voltage, E , decreases with increasing current, C , so that dE/dC is negative; at about 6.5 amps., dE/dC is zero, and if the current be increased beyond that value, dE/dC is positive, and the arc becomes stable. P. Küch and T. Retschinsky showed that the efficiency of the lamp expressed in Hefner's candles per watt, is relatively large and increases with the vap. press., and with the watt consumption—Fig. 8. The press. and temp. of the mercury arc lamp were studied by J. Stark and M. Reich, H. Buisson and C. Fabry, C. T. Knipp, L. Arons, etc. The potential gradient of the mercury arc lamp has been investigated by R. de Valbreuze, J. Pollak, A. Perot, J. Stark and co-workers, E. Warburg, A. P. Wills, P. C. Hewitt, etc.; and the luminescence and radiation of energy, by A. Perot and co-workers, C. Fabry and H. Buisson, H. Bordier, H. Rubens and O. von Baeyer, V. Henri, L. Grebe, C. D. Child, W. Matthies, H. Rubens and W. W. Coblentz, J. Pole, M. Boll, A. Tian, H. Busch, J. Stark, H. Herwig, and K. Burns. W. W. Coblentz and W. C. Geer's measurements of

FIG. 8.—Efficiency of Mercury Vapour Lamp with Variations of the Pressure of the Mercury Vapour.

the distribution of energy are illustrated by the diagram, Fig. 9. The visible radiation is confined principally to two sharp lines, Hg_a with $\lambda=0.546\mu$, and Hg_b with $\lambda=0.579\mu$. The light from the mercury arc is accordingly of a livid bluish-green colour, and it lacks the warmer and richer hues of ordinary light. This subject has been discussed by J. H. Gladstone, H. E. Ives, A. J. Marshall, etc. A. Günther-Schulze studied the cathode phenomena in the electric arc; G. E. Gibson and W. A. Noyes, the luminous discharge in mercury vapour; and A. Hörnli, the ultra-violet light from the mercury arc.

FIG. 9.—Spectrum of the Energy Radiation from the Mercury Arc.

J. W. Ritter²² placed mercury near the middle of the **electro-chemical series**, and G. Wiedemann believed that mercury is more readily charged with positive than with negative electricity. According to W. Hankel, if the potential difference—the **Volta effect**—between zinc and copper is 100, that of mercury with aluminium is 101 to 106; with zinc, 81; with cadmium, 62; with lead, 37; with tin, 30; with antimony, 12; with bismuth, 11; with nickel-brass, 6; with brass, 3; with iron, -3 to -11; with copper, -19; with gold, -29; with palladium, -34; with silver, -37; with coke, -41; and with platinum, -42. W. E. Ayrtton and J. Perry, O. J. Lodge, C. Hockin and H. A. Taylor, and R. B. Clifton measured the contact potential of mercury and copper; R. B. Clifton, against iron; and R. B. Clifton, and C. Hockin and H. A. Taylor, against zinc. H. Pellet found that against soft gold, the contact potential is -0.06 volt, and against hard gold, +0.04 volt. F. Exner and J. Tuma found the contact potential against sodium is 2.47; magnesium, 1.38; zinc, 1.08; aluminium, 0.98; lead, 0.72; tin, 0.67; iron, 0.56; copper, 0.33; silver, 0.18; platinum, 0.05; gold, 0.05; and carbon zero. A. Gouy found that the contact potential of mercury with its amalgams is zero, and with other metals very small. E. Obach obtained no current between mercury and zinc, cadmium, tin, platinum, or iron. C. Christiansen measured the potential difference of mercury against magnesium, aluminium, zinc, tin, lead, iron, copper, or carbon at 20° in the presence of air, hydrogen, oxygen, or carbon dioxide. E. Perucca measured the Volta effect in the Zn-Hg, Cd-Hg, Bi-Hg, and Sb-Hg couples in vacuo and in various gases; and with the Hg-Pt couple in air, nitrogen, carbon dioxide, and hydrogen.

J. Canton found that mercury is negatively charged when a piece of glass, shellac, amber, or calcspar is dipped into the liquid; according to J. P. Dessaignes, the results with shellac, silk, wool or glass, and mercury differ according to the degree of purity of the element. L. Hart found that mercury is negatively charged by friction on the walls of a capillary, and when it is broken up into beads by an air-blast. J. Dechant noted that mercury is electrically charged when filtered through leather, and this the more the finer the pores. A. Gaugain studied the charging of mercury with electricity by friction with other metals. E. Perucca found that a freshly made surface of mercury is strongly electrified positively if placed in contact with glass, paraffin, sealing-wax, ebonite, wool, etc., but after a time, the surface of mercury loses its positive charge, passes through a neutral stage, and then acquires a negative charge which gradually increases to a limiting value. A. Coehn and A. Lotz also found that mercury in vacuo is positively electrified with respect to glass. J. Heyrovsky studied the electrolysis of soln. of alkali or alkaline earth salts with mercury drops as electrode.

C. Matteucci²³ could detect no **thermoelectric force** between hot and cold mercury. The subject was further investigated by G. Gore, G. Magnus, F. C. Henrici,

V. de Heer, T. des Coudres, and A. Peltier. The thermoelectric force of mercury against liquid and solid amalgams was studied by A. Battelli. A. Seebeck, W. Hankel, P. Bachmetjeff, and J. Cumming have investigated the position of mercury in the thermoelectric series. Warm mercury and the cold metal give a current from hot to cold with bismuth, platinum, copper, silver, lead, tin, zinc, mercury, and gold; and from cold to hot with antimony, arsenic, and iron. The effect of press. has been studied by E. Wagner, E. Siegel, T. des Coudres, H. Agricola, A. H. Bucherer, and H. Hörig. The Thomson effect has been studied by W. Thomson, F. Braun, J. Königsberger and J. Weiss, H. Haga, P. Cermak, C. Schoute, and T. des Coudres. F. Braun found the thermoelectric force with the *lead-mercury* couple to be -3.93 microvolts at 50° ; K. Noll gave -4.03 . A. Matthiessen gave 2.52 for the *silver-mercury* couple between 4° and 48° , when that of the silver-copper couple is unity. E. Becquerel gave -0.000483 volt for the *copper-mercury* couple, and A. Gaugain found the e.m.f. rises more rapidly than the temp. G. Gehlhoff and F. Neumeier's value for the thermoelectric force of copper-mercury couple, $dE/d\theta$, is:

	-193°	-78.4°	-37.6°	0°	50.5°	99.9°	149.4°
$dE/d\theta$. . .	0	2.02	5.59	6.11	7.55	9.32	10.91μ volts

with a marked break at the m.p. E. Oosterhius studied the iron-mercury couple, and found at 16.2° the e.m.f. is 2692×10^{-7} volts at 98° , 15935×10^{-7} volt; and at 182.6° , 28280×10^{-7} volt; and the Peltier effect is 1.1644×10^{-3} grm. cal. at 18.45° ; 1.388×10^{-3} grm. cal. at 99.64° ; and 1.511×10^{-3} grm. cal. at 182.3° . P. Cermak's values for the Thomson effect $\times 10^7$ in cals. are -4.20 at 47° ; -5.11 at 71° ; -5.88 at 179° ; and -4.98 at 262° . K. Noll found at 100° the *mercury-platinum* couple gives 0 millivolt; E. Becquerel gave -0.07 and E. Wagner 0.04 millivolt. A. Battelli found for *zinc-mercury* and *brass-mercury* couples respectively -71.620 and -50.126 microvolts at 20° , rising to -1429.000 and -820.940 microvolts at 200° respectively. K. Noll found for a temp. difference of 100° , in microvolts, bismuth, -6705.4 ; ordinary *nickel*, -1643.3 ; purified *nickel*, -1448.37 ; *cobalt*, -1522.2 ; *nickel-brass*, -1079.9 ; *tin*, 391.44 ; *lead*, 402.5 ; *brass*, 439.38 ; *silver*, 690.88 ; *gold*, 713.35 ; *copper*, 726.62 ; *zinc*, 713.96 ; *cadmium*, 867.41 ; *iron*, 1592.2 ; *antimony*, 3379.6 ; and *carbon*, 1452 . W. Peddie and A. B. Shand found the thermoelectric current of solid mercury gives a curve nearly continuous with that of liquid mercury. P. Cermak measured the thermoelectric force and the Peltier effect of mercury against constantin. G. Gore, and C. R. A. Wright and C. Thompson measured the thermoelectric force of mercury against a number of salt solutions.

S. Marianini²⁴ placed mercury at the negative end of the series with respect to the difference of potential in sea-water acidified with $\frac{1}{100}N$ -sulphuric acid; A. de la Rive put mercury between tin and lead, and H. C. Oersted between arsenic and silver, with respect to dil. sulphuric acid. A. de la Rive put mercury between lead and silver with respect to conc. nitric acid; J. C. Poggendorff between silver and cupric sulphide with respect to a soln. of ammonium chloride; and between lead and palladium with respect to a soln. of potassium cyanide. W. Ostwald found mercury to be electronegative with respect to acids; and J. Brown, with respect to electrolytes generally. A. von Antropoff found that in hydrogen peroxide, mercury becomes more electropositive in the presence of alkalies, and more electronegative in the presence of acids.

H. Pellat found the potential difference of mercury towards mercurous nitrate is zero, but it may be considerable in the presence of other electrolytes. C. Hockin and H. H. Taylor found that when mercury is alloyed with one or more metals, it becomes very much more electropositive towards dil. sulphuric acid, and soln. of zinc sulphate; S. Lindeck, indeed, found that 0.0005 per cent. of foreign metal had an appreciable action, and this the more the more positive the added metal. W. C. Sabine and G. Lippmann found that when purified and impure mercury are

immersed in vessels in water, and in electrical contact, a current flows through the water to the impure mercury. If two mercury electrodes in electrical contact are dipped at different times in a conducting but indifferent liquid—water, alcohol, glycerol, salt-soln., hydrochloric acid, etc.—G. Quincke found that a current is produced.

N. T. M. Wilsmore estimated the **electrolytic potential** of mercury against a normal ionized soln. to be -0.750 volt; W. Ostwald gave -0.99 volt; and B. Neumann gave against a sat. soln. of *mercurous sulphate*, -0.980 volt. Other measurements have been made by W. E. Ayrton and J. Perry, V. Rothmund, E. Rothé, C. R. A. Wright and C. Thompson, F. Auerbach, L. Sauer, etc. B. Neumann found the potential of mercury against a soln. of *mercurous nitrate* to be -1.028 volt, or -1.027 volt, according to N. T. M. Wilsmore. Other measurements have been made by F. Fischer, R. Behrend, H. Pellat, C. R. A. Wright and C. Thompson. For *mercurous chloride*, the normal calomel electrode, W. Ostwald and W. C. McC. Lewis gave 0.61 ; and L. Sauer found for $\text{Hg} | \text{N-KCl}, \text{HgCl}$ -electrode, 0.560 volt at 18° . W. Palmaer, N. T. M. Wilsmore, C. R. A. Wright and C. Thompson, H. A. Fales and W. A. Mudge, F. H. Getman, H. Freundlich and E. Mäkel, J. Billitzer, R. Luther, E. Rothé, E. Amelung, N. E. Loomis, and S. F. Acree, F. Auerbach, etc., have measured the potential of the calomel electrode. The temp. coeff. has been measured by L. Sauer, G. W. Coggeshall, and T. W. Richards. F. Auerbach, R. Luther and F. Pokorny, F. G. Donnan and A. J. Allmand, etc., measured the potential of the electrodes $\text{Hg} | \text{HgO}, \text{KOHaq.}$, and of $\text{Hg} | \text{HgO}, \text{KOHaq.}$ R. Luther found that the potential of a soln. of a mercurous salt and mercury is about 223 times that of a soln. of a mercuric salt of the same dilution. F. M. G. Johnson and N. T. M. Wilsmore found the potential of mercury against water to be -0.329 volt, and W. Hankel found that if the contact potential of Zn-Cu be 100, that of mercury against water is at first -6 , falling after some time to -30 ; other measurements were made by F. Exner.

R. Blondlot and E. Bichat found for *sulphuric acid*, 0.842 volt; H. Pellat, F. Paschen, and A. König also measured the potential of mercury against sulphuric acid. F. Exner measured the potential of mercury against *chlorine water*, *bromine water*, and *iodine water*; F. Exner, and F. Paschen against *hydrofluoric acid*; F. Paschen, F. Exner, and A. König, against *hydrochloric acid*; F. Exner and V. Rothmund, against *hydrobromic acid*; F. Exner, against *hydriodic acid*; F. Paschen, and R. Behrend, against *potassium hydroxide*; A. König, F. Paschen, and R. Behrend, against *sodium hydroxide*; C. Immerwahr, against *barium hydroxide*; F. Paschen, C. Immerwahr, and R. Behrend, against *potassium chloride*; R. Behrend, against *potassium bromide*; F. Paschen, R. Behrend, V. Rothmund, and H. Brandenburg, against *potassium iodide*; R. Behrend, against *complex iodides*; C. R. A. Wright and C. Thompson, against the *silver halides* suspended in soln. of the corresponding halide; and *zinc chloride*, *cadmium chloride*, and *mercurous bromide and iodide* suspended in soln. of the corresponding zinc halide; F. M. G. Johnson and N. T. M. Wilsmore, of a soln. of mercuric iodide in *liquid ammonia*. A. König, and F. Paschen, against *nitric acid*; G. Gore, against *ammonium, potassium, and sodium nitrates*; C. R. A. Wright and C. Thompson, against *silver nitrate*; G. Gore, against *strontium and barium nitrates*; S. Labendzinsky, against *zinc nitrate*, *cadmium nitrate*, *lead nitrate*, *cobalt nitrate*, and *nickel nitrate*. F. Paschen, and G. Gore, against *potassium sulphate*; A. König, and G. Gore, against *sodium sulphate*; G. Gore against *ammonium sulphate*, *ammonium aluminium sulphate*, *sodium selenate*; and *sodium sulphite*; A. König, against *magnesium sulphate*; A. König, and S. Lindeek, against *zinc sulphate*; G. A. Hulett and R. E. de Lury, against *cadmium sulphate*; F. Paschen, against *ferrous sulphate*. F. Paschen, R. Behrend, and G. Gore, against *sodium carbonate*; F. Paschen, C. Immerwahr, and G. Gore, against *potassium carbonate*; F. Paschen, C. Immerwahr, S. B. Christy, and V. Rothmund and G. Gore, against *potassium cyanide*; F. Paschen, and R. Behrend, against *mercuric cyanide*; C. Immerwahr, R. Behrend, and V. Rothmund, against *potassium thiocyanate*. C. Immerwahr, and R. Behrend measured the potential of mercury against soln. of *potassium dichromate*; C. Immerwahr, and R. Behrend, against *sodium hydrophosphate*; C. Immerwahr, against *ammonia complexes*; R. Behrend, against *ammonium chloride*; R. Behrend, against *ammonium hydroxide*; C. Immerwahr, against *hydrogen sulphide*; C. Immerwahr, R. Behrend, and V. Rothmund, against *sodium sulphide*; H. Brandenburg against *potassium sulphide*; R. Behrend, against *potassium tartrate*; R. Behrend, against *potassium oxalate*; G. Gore, against *formic acid* and *sodium formate*; R. Behrend, against *urea*; R. Behrend,

H. Brandenburg, and G. Gore, against sodium thiosulphate ; G. Gore, against sodium, and ammonium phosphates ; sodium diborate ; and boric acid.

K. Bornemann²⁵ measured the e.m.f. of the cell $\text{Hg} \mid \text{H}_2\text{O}_2 \mid \text{Hg}$. E. Neumann studied the cell with Hg and H_2SO_4 against Hg and a sat. soln. of mercurous sulphate, and found it to be remarkably constant. E. C. Sullivan studied the cell with $\text{Hg} \mid \text{HgCl}$, and hydrochloric acid against $\text{Hg} \mid \text{HgCl}$ and a soln. of potassium chloride ; and A. Lapworth and J. R. Partington against $\text{Hg} \mid \text{HgCl}$ and hydrochloric acid (concentration cell) ; V. Rothmund studied the cell with $\text{Hg} \mid \text{HgCl}$, and a soln. of potassium chloride against mercury and a sulphuric acid soln. of mercurous sulphate ; S. Bugarszky against mercury and a soln. of mercurous bromide in potassium bromide, of mercurous iodide in potassium iodide, of mercuric sulphide in potassium hydrosulphide ; of mercurous nitrate in potassium nitrate, of mercurous oxide in potassium hydroxide, and of mercurous sulphate in potassium sulphate ; and R. Luther and F. Pokorny against mercury and a soln. of mercurous sulphate in potassium sulphate. J. von Hepperberger studied conc. cells of zinc sulphate soln. with mercury electrodes ; E. Biron, conc. cells of cadmium chloride with calomel electrodes ; and R. Abegg, and M. S. Sherill, conc. cells of mercuric bromide, and iodide, and mercuric cyanide with mercury electrodes ; A. Ogg studied cells with mercury and a nitric acid soln. of mercurous nitrate against mercury with a nitric acid soln. of silver nitrate : S. Bugarszky, cells with mercury and a soln. of mercurous bromide in potassium bromide, of mercurous iodide in potassium iodide, or of mercurous oxide in potassium hydroxide, against mercury and a potassium acetate soln. of mercurous acetate. S. W. J. Smith and H. Moss studied the e.m.f. of soln. with electrodes of mercury at rest and in motion. F. Paschen found that a mercury anode polarizes more quickly in hydrochloric acid than in sulphuric acid, and he attributed this to the formation of a coherent film of calomel ; A. W. Laubengayer also showed that the apparent irreversibility of the calomel electrode is due to the formation of a strongly adsorbed film of mercurous chloride on the surface of the mercury anode ; this film offers a high resistance to the passage of the current.

The electromotive force of various cells with mercury as one electrode and another metal as cathode, and different acids, bases, and salt soln. as electrolytes, has been studied by A. Oberbeck and J. Edler.²⁶ F. Streintz measured the e.m.f. of mercury and sulphuric acid against silver and silver sulphate ; copper and copper sulphate ; bismuth and bismuth sulphate ; cobalt and cobalt sulphate ; tin and stannous sulphate ; cadmium and cadmium sulphate ; zinc and zinc sulphate ; and against magnesium and magnesium sulphate. M. H. Jacobi measured the e.m.f. of mercury and nitric acid against a soln. of potassium cyanide and zinc, copper, cadmium, tin, silver, nickel, antimony, lead, and mercury. The cell with mercury and a soln. of mercuric oxide in one of sodium hydroxide against the hydrogen electrode has been investigated by J. N. Brönsted, and R. Luther and F. Pokorny ; the cell with mercury and a soln. of mercurous sulphate in sulphuric acid against the hydrogen electrode by R. Luther and F. Pokorny, and A. C. Chapman and H. D. Law ; mercury and a soln. of mercuric sulphate against copper or copper amalgam and cupric sulphate by L. W. Oeholm ; mercury and a soln. of zinc sulphate against zinc by J. Moser, J. M. Gaugain, and C. Hockin and H. A. Taylor ; mercury and a soln. of cadmium sulphate against cadmium by C. Hockin and H. A. Taylor ; mercury and mercuric chloride against zinc chloride and zinc by H. von Helmholtz, and V. Buscemi ; mercury and mercurous chloride against zinc and zinc chloride, cadmium and cadmium chloride, copper and cupric chloride, or iron and ferrous chloride by S. Czapsky, T. Godlewsky, and F. Streintz ; mercury, mercurous chloride, and zinc chloride against lead chloride and lead by P. Chroustchoff and A. Sitnikoff ; mercury and a carbonic acid soln. of mercuric carbonate against zinc by G. A. Hulett ; mercury and cupric sulphate against copper by J. Moser, N. A. Puschin, C. L. Speyers, and J. C. Poggendorff ; mercury and a sat. soln. of zinc sulphate in sulphuric acid against zinc and zinc sulphate by

W. Kistiakowsky ; mercury and a soln. of mercurous chloride in potassium chloride against zinc and zinc sulphate by W. Kistiakowsky ; against cadmium and cadmium chloride by E. Biron ; against silver, silver chloride, and cadmium chloride by E. Biron ; against silver chloride and silver by P. Chroustchoff and A. Sitnikoff ; and against hydrochloric acid and platinum by N. E. Loomis and S. F. Acree ; mercury and mercurous chloride against lead and lead chloride by F. Pollitzer, E. Cohen, and R. Luther ; and against silver chloride and silver by F. Pollitzer, and J. N. Brönsted. J. Regnault measured the e.m.f. of mercury and of soln. of potassium iodide with chlorine, bromine, or iodine against carbon and a soln. of potassium iodide. M. le Blanc measured the e.m.f. of the cells with mercury and a normal soln. of the chlorides of sodium, potassium, lithium, magnesium, calcium, strontium, barium, and zinc against an amalgam with the corresponding metal. C. Hockin and H. A. Taylor studied the e.m.f. of many amalgams and alloys against mercury and sulphuric acid ; F. Paschen, the e.m.f. of mercury and a soln. of zinc sulphate against zinc amalgam ; and C. L. Speyer, the e.m.f. of the same cell with soln. of various salts and acids.

F. M. G. Johnson and N. T. M. Wilsmore²⁷ studied cells with soln. of liquid ammonia ; L. Kahlenberg, in pyridine ; and J. Neustadt and R. Abegg, in methyl alcohol, and ethyl alcohol ; W. Negbauer studied cells with fused salts ; and G. Meyer, cells with glass as the electrolyte.

The unit of electrical press., the volt, is defined by the Board of Trade as that which if steadily applied to a conductor whose resistance is one ohm, will produce a current of one ampère, and is represented by $0.6974(1000/1434)$ of the electrical press., at a temp. of 15° , between the poles of the standard voltaic cell known as Clark's and set up in a specified way. The e.m.f. of a standard cell should be readily reproduced ; it should not change with age ; and the changes should vary in a definite way when the temp. changes. The silver chloride cell of W. de la Rue²⁸ was used at one time as a standard cell, but it proved to be unsatisfactory. F. M. Raoult, O. J. Lodge, and J. A. Fleming attempted to use a form of Daniell's cell as a standard, but it was proved to be troublesome. Forms of the cell proposed in 1873 by L. Clark have proved to be the most successful standard cell.

Four standard cells with a mercury electrode have attracted some attention, A. Gouy's, H. von Helmholtz's, E. Weston's, and L. Clark's. The general characters of standard cells have been discussed by W. Jäger,²⁹ G. A. Hulett, K. Kahle, J. Klemencic, C. J. J. Fox, P. J. H. van Ginneken, T. Wulf, etc. The thermodynamics of standard cells have been studied by E. J. Cohen and co-workers, R. A. Lehfeld, H. Rupp, L. G. Gouy, W. Jäger, H. von Helmholtz, D. McIntosh, G. A. Hulett.

In Clark's standard cell,³⁰ $\text{Zn} \mid \text{ZnSO}_4 \mid \text{Hg}_2\text{SO}_4 \mid \text{Hg}$, the reaction $\text{Zn} + \text{Hg}_2\text{SO}_4 \rightleftharpoons \text{ZnSO}_4 + 2\text{Hg}$, goes from left to right during the discharge, and F. Pollitzer gives 82,402 cal. for the thermal value of this reaction at 18° . The preparation of cells of different form has been described by R. T. Glazebrook and S. Skinner, A. E. Köhler, H. L. Callendar and H. T. Barnes, H. S. Carhart, K. Feussner, Lord Rayleigh, W. Jäger, K. Kahle, J. Swinburne, W. R. Cooper, etc. E. Cohen and P. J. H. van Ginneken have shown that the cell gives good results between 20° and 38° . The e.m.f. at 15° was found to be 1.4378 volts by L. Clark ; 1.4329 volts by H. S. Carhart ; 1.4345 volts by Lord Rayleigh ; 1.4344 volts by R. T. Glazebrook and S. Skinner ; 1.4322 volts by K. Kahle ; 1.4328 volts by W. Jäger and K. Kahle ; 1.4333 volts by H. S. Carhart and K. E. Guthe ; 1.434 volts by A. von Ettinghausen ; and 1.4323 volts by W. E. Ayrton, T. Mather, and F. E. Smith. G. A. Hulett found 1.4240 volts at 25° and 1.43300 volts at 15° . The e.m.f. has been studied by many others—H. T. Barnes, F. Pollitzer, W. Kistiakowsky, S. Lindeek, F. S. Spiers, B. S. Twyman, and W. L. Walters, A. P. Trotter, E. J. Cohen, etc. W. Jäger and K. Kahle gave for the effect of temp. at θ° between 0° and 30° $E = 1.4328 - 0.00119(\theta - 15) - 0.000007(\theta - 15)^2$ volt ; H. L. Callendar and H. T. Barnes gave $E = E_{15} - 0.001200(\theta - 15) - 0.0000062(\theta - 15)^2$; and Lord

Rayleigh gave $E = E_{15^\circ} \{1 - 0.00077(\theta - 15)\}$. E. Cohen and L. R. Sinnige studied the effect of press.

The relatively large temp. coeff. of Clark's cell is due to the large variation in the solubility of zinc sulphate with variations of temp., and in order to reduce the temp. coeff., E. Weston³¹ recommended cadmium sulphate because the solubility changes relatively little with temp. He also used an alloy of cadmium in place of zinc; and he thus reduced the temp. coeff. to 0.01 per cent. The combination in **Weston's standard cell** is therefore $\text{Cd} | \text{CdSO}_4 | \text{Hg}_2\text{SO}_4 | \text{Hg}$, and the reaction is $\text{Cd} + \text{Hg}_2\text{SO}_4 \rightleftharpoons \text{CdSO}_4 + 2\text{Hg}$, from left to right when the cell is discharging. The effect of using cadmium amalgam has been studied by E. Cohen, J. Obata, F. E. Smith, S. W. J. Smith, C. H. Wind, H. C. Bijl, G. A. Hulett, etc. The construction of the cell has been discussed by W. Jäger and co-workers, E. Cohen and co-workers, G. A. Hulett and co-workers, H. T. Barnes, C. H. Wind, P. J. H. van Ginneken, F. E. Smith, J. Henderson, A. Dearlove, E. Cohen and T. Kohnstamm, J. Blondin, H. C. Bijl, etc. The effect of different cadmium amalgams on the e.m.f. of the cell has been treated by W. Reinders, F. E. Smith, H. C. Bijl, W. Jäger and S. Lindeck, E. Cohen and co-workers, etc. According to J. Boerema, the e.m.f. of the cell at 17° is 1.01833 volts; E. Warburg gave 1.0183 volts at 20° ; P. Janet and co-workers, 1.01836 volts at 20° ; W. E. Ayrton and co-workers, 1.018305 volts at 17° ; W. Jäger, 1.0190 volts; E. Cohen, 1.0185 volts at 25° ; G. A. Hulett, 1.01843 volts at 25° ; and R. de Baillèhache, 1.01836 volts at 17° . Other observations have been made by F. E. Smith, S. N. Taylor, W. Jäger and co-workers, W. Marek, etc. A. N. Shaw and H. E. Reilley studied the ageing of the Weston cell. S. W. J. Smith found the temp. coeff. of the cell at 5° to be zero, above 5° it is positive, and below, negative. F. A. Wolff gave for the e.m.f. of the cell at θ° , $E = 1.0184 - 0.00004075(\theta - 20) - 0.06944(\theta - 20)^2 + 0.0898(\theta - 20)^3$; F. E. Smith, $E = E_{17^\circ} - 0.0000345(\theta - 17) - 0.0666(\theta - 17)^2$; W. Jäger, $E = 1.0186 - 0.0438(\theta - 20) - 0.0665(\theta - 20)^2$. Other observations have been made by W. Jäger and co-workers, H. von Steinwehr, H. T. Barnes, P. Janet and R. Jouast, H. C. Bijl, A. Dearlove, S. Czapsky, E. Cohen and H. R. Krüy, etc.

Attempts³² have been made to prepare standard cells of exactly one volt, but the practical advantage does not amount to much. In **Helmholtz's standard cell**, $\text{Zn} | \text{ZnCl}_2 | \text{HgCl} | \text{Hg}$, the e.m.f. is nearly one volt when the sp. gr. of the soln. of zinc chloride is 1.391 at 15° . An increase of 16 per cent. in the sp. gr. of the soln. diminished the e.m.f. by 3.5 per cent. Cells of this type, with unsaturated soln., should be sealed so that evaporation may not change the sp. gr. of the soln. H. S. Carhart gave for the e.m.f. at θ° , $E = 1 + 0.000094(\theta - 15)$, showing that the temp. coeff. is positive. According to W. Hibbert, the temp. coeff. is 0.000085 volt per degree. The cell has also been studied by W. Ostwald, and W. Jäger. **Gouy's standard cell**,³³ $\text{Zn} | \text{ZnSO}_4 | \text{HgO} | \text{Hg}$, is not reversible. The e.m.f. is about 1.4 volts, with a negative temp. coeff. of about 0.0002 volt per degree. S. Lindeck, R. T. Glazebrook and S. Skinner, W. Jäger, C. Limb have studied the cell. According to W. Jäger, the cell $\text{Cd} | \text{CdCl}_2 | \text{HgCl} | \text{Hg}$, with an e.m.f. of about 0.75 volt, and a negative temp. coeff. of 0.00025 volt per degree, is not suitable as a standard cell. J. Obata studied the e.m.f. of the standard cell $\text{Hg} | \text{Hg}_2\text{SO}_4, \text{CuSO}_4 | \text{Cu amalgam}$.

W. Ostwald³⁴ gave -20 Cals. for the **heat of ionization** of the Hg^+ -ion from the element, and W. R. Bousfield and T. M. Lowry -19.28 Cals. for the Hg^+ -ion, while that of hydrogen is -0.6 Cal. W. Ostwald also gave -20500 cals. per valence. J. Stark, A. S. Eve, P. Drude, R. Pohl, R. Fürstenau, R. Schenk, etc., have studied the relation between the electrons and molecule of mercury. The **transport numbers** of ions have been measured by E. Rieger, J. F. Daniell and W. A. Miller, W. Hittorf, A. Chassy, C. L. Weber, J. Moser, G. Kümmell, R. Gans, P. Straneo, and S. Lussana. The **electrochemical equivalent** of mercury has been measured by R. Abegg, H. Buff, etc.; 3.7352 grms. of mercury separate per ampère-hour from soln. of mercuric salts.

The **decomposition voltages** of many mercury salts have been measured by

R. Abegg and G. Bodländer, A. Coehn and E. Neumann, E. Abel, E. Bose, J. E. Root, F. Glaser, W. Kettembeil, W. D. Bancroft, etc.³⁵ The electrolytic **solution pressure** is given as 3.1×10^{-16} atm. by B. Neumann; and the soln. press., that is, the excess press. against the press. of the ions, calculated by W. Ostwald from the observations of F. Braun and C. R. A. Wright and C. Thompson, is approximately 10^{-15} atm. The **overvoltage of hydrogen** on a mercury electrode is about 0.8 volt. corresponding with bivalent mercury; 0.4 volt corresponding with univalent mercury; and zero voltage corresponding with non-valent mercury. According to E. Newbery:

The first state is produced by, and is permanent at, low-current densities, and is generally shown by fresh mercury. The second state is shown by mercury which has been kept for some time in contact with dil. acid, and appears to be unstable when a current is flowing. It may be due to the formation of traces of mercurous salt absorbed on the mercury surface and also carried into the body of the mercury by movements due to change of surface tension. This salt on decomposing would tend to give the hydride corresponding with univalent mercury, and therefore the lower overvoltage. The third state is permanent at high-current densities, and when once acquired takes a considerable time for its removal. Its sudden appearance is accompanied by an equally sudden change in the size of the bubbles of gas liberated, from large to very small.

The overvoltage of mercury has been measured by W. A. Caspari,³⁶ A. Coehn, J. Tafel, E. Müller, S. Dunnill, E. Newbery, H. G. Möller, J. W. Walker and C. S. Paterson, and G. N. Lewis and R. F. Jackson. G. Carrara found 0.77 volt in methyl alcohol soln., and 0.56 volt in ethyl alcohol soln. The **polarization** of the mercury cathode has been studied by E. Warburg,³⁷ W. Lietzau, E. Rothé, J. Roschkowsky, M. le Blanc, G. Lippmann, E. Bouty, F. Streintz, J. Tafel, F. Teltscher, G. N. Lewis and R. F. Jackson, etc. S. Dunnill studied the overvoltage of the mercury cathode. S. Magrini observed a curious effect of electrolytic polarization and depolarization with the consequent variations in the surface tension and form of a drop of mercury:

When the end of a piece of clean magnesium wire is brought just into contact with a drop of mercury placed in a basin or watch-glass and covered with 0.1–0.2 per cent. hydrochloric acid, the mercury at once begins to undergo rhythmic contraction and distensions, the movements continuing until the magnesium wire is removed. If the end of the wire is central to the upper part of the drop, the rhythmic movement produces a surface undulated in concentric rings, whereas if a non-central position is occupied by the wire, an undulating ellipsoidal form results, this undergoing rhythmic contraction and distension in directions mostly perpendicular to one another. The rapidity of the oscillations varies with the magnitude of the drop. The same phenomenon is observed if the hydrochloric acid is replaced by a soln. of potassium hydroxide, sodium carbonate, ammonia, etc., but it seems necessary that hydrogen should be evolved by either direct or secondary chemical action. The phenomenon is especially marked with an aluminium wire and a soln. of potassium cyanide. With an iron wire and hydrochloric acid soln., the movement of the mercury occurs only if the wire is applied to the side of the mercury where the **curvature** of the drop is greater than at the upper surface.

E. Perucca studied the **electrification** of mercury by friction; M. König, the electrostatic charge carried by fine particles of mercury falling in different gases; H. Schüler, the cathode and anode drop in mercury vacuum arc; H. Sponer, the effect of **colliding electrons** on the mercury atom; and J. S. van der Linden, J. K. Robertson, and J. von Kowalsky, the **electrodeless discharge** in mercury vapour. E. Bouty measured the **dielectric cohesion** of mercury vapour. Y. T. Yao studied the low voltage arc in mercury vapour.

According to M. Faraday,³⁸ mercury is diamagnetic. G. Quincke found the **magnetic susceptibility** to be, air unity, -2.6×10^{-6} vol. units at 19° ; S. Meyer found -2.1×10^{-6} vol. units at 15° ; K. Honda, -0.193×10^{-6} mass units at 18° ; and G. Meslin, 0.19×10^{-6} mass units; K. Honda said that the magnetic susceptibility remained constant between atm. temp. and the b.p., but M. Owen found it to increase numerically in passing from -170° to -39° . A. Dufour found a magnetic field lengthened the stream of mercury flowing from a capillary tube.

C. Maurain used mercury as an electromagnetic screen. G. Berndt found that

a magnetic field scarcely affected the electrical resistance of mercury; and T. des Coudres likewise observed no change in the thermoelectric properties in the magnetic field. A. Dufour studied the rotation of the arc in a magnetic field, and A. Perot, the effect of a magnetic field on the luminosity of the arc light in a vacuum tube. P. Pascal measured the magnetic sensitiveness; W. N. Fenninger, the **Hall effect**; and H. Geipel, the magnetic properties at the temp. of liquid air.

§ 4. The Chemical Properties of Mercury

Mercury is not altered by shaking it in an atm. of hydrogen. J. J. van Laar¹ found a slight absorption whereby the metal acquires an electric charge, and H. Wislicenus stated that 10^{14} times less hydrogen is occluded by mercury than by copper. V. L. Chrisler also found that the press. in a hydrogen tube, fitted with a mercury anode and nickel cathode, fell from 2.41 to 2.365 mm. in 7 mins., and when helium is substituted for hydrogen, the decrease of press. is twice as great.

M. Berthelot could detect no sign of any reaction between **argon** or **helium** and mercury, nor could J. Stark detect any action of argon on mercury in a stream of canal rays. According to F. Fischer and F. Schröter, argon does not react with mercury when an arc with mercury as cathode and carbon as anode is made under liquid argon. A black cathode dust of mercury is formed.

O. Loew,² and I. Walz obtained a pasty mass by shaking zinc amalgam with a soln. of mercuric chloride containing platinic, palladous, or auric chloride. Air must be excluded, and the mixture kept cold. According to E. Duter, the electrolysis of water with a mercury cathode and platinum anode gives a pasty mass which gives hydrogen when the current is interrupted; and A. Potier observed similar phenomena in the electrolysis of a soln. of the nitrate. The product decomposes slowly when dried or when kept under water; and, according to O. Loew, the mercury loses 150 times its vol. of hydrogen, and the mass swells considerably during the evolution of the gas. It reduces ferric salts and ferricyanides, and decolorizes potassium permanganate. According to G. Meyer, and C. A. Seely there are no grounds for assuming this product is a *mercury hydride*. W. Duane and G. L. Wendt found that immediately hydrogen has been bombarded by α -radiations the gas is activated so that it reacts with mercury, forming yellow crystals of what may be mercury hydride—vide 1. 7, 7. F. Paneth and co-workers observed no sign of the formation of a gaseous mercury hydride by the action of activated hydrogen. G. N. Lewis and R. F. Jackson deduced the existence of *hydrogen amalgam* from the behaviour of the mercury cathode during the separation of hydrogen in electrolysis.

A. Matthiessen and C. Vogt³ found that no **oxygen** is absorbed by purified mercury, nor is the mercury affected by shaking it with **air** or oxygen; C. Christiansen, and J. M. Crafts found very little action when purified mercury is shaken with oxygen or air; and M. de Broglie detected some oxidation when the shaking is vigorous. J. Stark found that mercury takes up oxygen when exposed to the canal rays. E. Amagat found that at ordinary temp. no action occurs even at high press. if the oxygen be dry. M. Berthelot found mercury is superficially oxidized by oxygen or air, and the action is accelerated by the presence of acids; and D. Macaluso said that the oxidation occurs only in the presence of water vapour. According to H. B. Baker, mercury vapour, under ordinary circumstances, contains only atoms of mercury which exhibit little tendency to combine with oxygen. The vapour, however, is ionized in the mercury vapour lamp, and when the current is cut off and oxygen is admitted shortly afterwards, the mercury becomes covered with a layer of mercuric oxide. Since the temp. of the lamp is much below that at which ordinary mercury vapour combines with oxygen, it is evident that in this case ionization can bring about chemical action. The oxidation of heated mercury has been previously discussed—1. 1, 16; 1. 8, 2.

According to L. Gmelin, when the two poles of Hare's deflagrator are made to dip into two vessels full of mercury, and the mercury allowed to run in a fine stream through a narrow opening from the upper to the lower vessel, visible combustion takes place. According to R. Hare, the blue light which is seen whenever the circuit of a powerful galvanic battery is closed by dipping the connecting wire into mercury, is likewise due to combustion of the mercury. C. F. Schönbein found that mercury acts in the presence of oxygen as a catalytic agent upon some colouring matters.

Oxygen free from ozone does not affect the mirror-like surface of mercury, but the latter is readily attacked by dry **ozone**. According to A. Volta, when a tube of mercury is brought in contact with dry ozonized oxygen, the meniscus instantly disappears, and the surface becomes quite plane; after a few minutes' contact with the ozone, however, the edges become depressed, and the meniscus again reappears with a clean surface, the convexity gradually increasing until it far exceeds the normal curvature; this lasts for a couple of hours, and then the meniscus returns to its ordinary state. This phenomenon the author believes to be electrical, the period of maximum convexity corresponding with the maximum polarity of the metal; this, as in the case of other metals, is negative, but there is no permanent deflection.

Analogous results are obtained with moist ozone, but they are much less strongly marked. According to A. von Antropoff, if ozonized oxygen be passed through mercury, the latter becomes pasty and appears like tin-amalgam. It has been stated that ozone reacts with mercury, forming mercurous oxide, Hg_2O . W. Manchot and W. Kampschulte's observations are indicated under ozone—1. 14, 6.

According to M. T. Lecco, **water vapour** is not decomposed by mercury. D. Macaluso found that air-free water-vapour does not affect mercury; but with a mixture of air and water-vapour oxidation takes place, with the production of the well-known grey pellicle of suboxide. This action is analogous to the formation of mercurous chloride when mercury is left in contact with gaseous hydrogen chloride or its aq. soln. in presence of air, whereas in pure hydrogen chloride, or its pure aq. soln. perfectly deprived of air, no such formation takes place. A. Wiggers,⁴ and E. F. Anthon believed that mercury is slightly soluble in boiling water, because the liquid which is obtained by decantation from the mercury, when conc. by evaporation, gives the reactions of that element. C. Paton, and J. Girardin failed to detect mercury in water which had been boiled with that element; and L. Gmelin, and E. Riegel also showed that there is no foundation for assuming that mercury is soluble in water, because, when water is poured upon mercury, boiled down to one-half, decanted, then left to stand for several days, again decanted, and thrown upon a thick paper filter, small quantities of mercury, sufficient to silver gold-leaf, remain on the filter; but the filtrate, when mixed with nitric acid and evaporated, shows no trace of mercury. If C. Barfoed's statement be true that mercury can diffuse through a film of water at ordinary temp., the metal must be soluble in that menstruum. This is confirmed by A. Christoff's observation that mercury can dissolve in and diffuse through water which contains air, nitrogen, carbon dioxide, sulphuric acid, potassium hydroxide, and also through benzene, nitrobenzene, or alcohol. The diffusion of mercury was proved by the reduction of a soln. of auric chloride contained in a separate vessel. It was so shown that mercury left for a long time in contact with water suffers a slight loss in weight, although the amount of mercury retained by the water is too small to be detected. F. Fischer also made observations on the "chemical soln. press." of mercury. According to C. F. Schönbein, ozone—or is it hydrogen peroxide?—is formed when mercury is shaken with air and water, and on adding potassium iodide, a blue colour appears and potassium mercuric iodide is formed; and, added K. Voit, if sodium chloride is present, sodium mercuric chloride is formed and guaiacum tincture is coloured blue. The presence of mercury was found by W. van Rijn to accelerate the attack of iron, magnesium, and particularly aluminium on water, but not the attack by zinc or nickel. O. P. Watts and N. D. Whipple included mercury in their study of the action of various reagents on zinc—*q.v.*

C. F. Schönbein⁵ found that guaiacum tincture is coloured blue by hydrogen peroxide in the presence of mercury. According to J. A. Kappers, and B. J. Boerwiger, when mercury is shaken with a soln. of **hydrogen peroxide**, the meniscus is flattened, and a film of black powder—a mixture of mercurous and mercuric oxides—is formed. T. Fairley found that the presence of hydrogen peroxide favours the dissolution of mercury in acids; and with hydrochloric acid, mercurous chloride is formed. When mercury is covered with a 10 per cent. soln. of purified hydrogen peroxide, a bronze-yellow film appears on the surface of the metal, and the development of oxygen begins. According to G. Bredig and co-workers—E. Wilke, and J. Weinmayr—the catalytic decomposition of hydrogen peroxide by mercury proceeds rhythmically with a regularly increasing and decreasing velocity. It is estimated that the minimum thickness of the surface film of active mercury is 3×10^{-8} cms. It is assumed that the **periodic reaction** is conditioned by the formation and decomposition of a film of what is probably mercurous oxide, for if agents which dissolve this oxide are present the pulsating action ceases—sodium sulphate or carbonate, potassium nitrate or chlorate act vigorously, acids, or potassium chloride or bromide act feebly. The optimum alkali addition is from

10^{-3} to 10^{-4} mol per litre. Temp. has a great influence; cooling increases the period of oscillation, warming makes the reaction aperiodic. Reducing the press. lessens, and illumination raises the activity. The addition of 4×10^{-5} to 2×10^{-5} mol of alkali chloride per litre paralyzes the action; sulphates retard the action; and nitrates have no influence. During the periodic action, the electrolytic tension of the mercury varies periodically. The theory of the action has been discussed by A. von Antropoff, E. Wilke, C. Fredenhagen, and T. Okaya. According to D. Borar, a soln. of **sodium dioxide** is not affected by mercury.

According to M. C. Schuyten,⁶ the **halogen** in mercuric chloride, bromide, or iodide can be replaced by the other halogens even in the presence of an excess of the salt; the only exception is in the case of mercuric bromide and iodine, for the bromine is not displaced by the iodine. According to W. A. Shenstone, the presence of moisture is not necessary for the halogens to react with mercury. J. Schröder also found that the halogens are specially reactive with mercury salts dissolved in pyridine. The actions of **fluorine** and **hydrogen fluoride**; of **chlorine** and **hydrogen chloride**; of **bromine** and **hydrogen bromide**; and of **iodine** and **hydrogen iodide** on mercury, will be discussed in connection with the preparation of the corresponding mercury halides. G. Reboul showed that when chlorine is much diluted with an inert gas, and passed over mercury, no marked production of conducting ions occurs; and that the vapour of chlorine, bromine, or iodine, diluted with an inert gas, attacks a meniscus of mercury most vigorously where the curvature is greatest. K. Strzyzowsky has also made observations on the action of iodine on mercury. J. Schröder noted that the mercury formed by the action of pyridine on mercurous salts is immediately converted by iodine into mercuric iodide, which then passes into soln. R. Varet found mercury dissolves in a potassium iodide soln. of iodine, and, according to R. G. van Name and G. Edgar, in a potassium bromide soln. of bromine. R. S. Norris and F. G. Cottrell found that liquid hydrogen iodide rapidly dissolves mercury at ordinary temp. with the evolution of hydrogen and the formation of both iodides. According to W. Nernst, A. Harding, and F. Dolezalek, conc. **hydrochloric acid** dissolves mercury with the evolution of hydrogen; and, according to A. Harding, **hydrobromic acid** dissolves mercury. J. B. Hannay found that **iodine monochloride** forms mercuric chloride and iodide. J. J. Sudborough found that **nitrosyl chloride**, NOCl, and mercury, in a sealed tube, in the cold, form golden plates which decompose on opening the tube, furnishing mercuric chloride and nitrosyl chloride. According to P. Nicolardot, **sulphur dichloride**, S_2Cl_2 , acts on mercury like hydrogen chloride, but if the attack is slow, mercury sulphide is formed; H. B. North found **thionyl chloride** does not act on mercury in the cold, but with a large excess, a few hours' heating at 150° furnishes mercuric chloride, sulphuryl chloride, and sulphur dichloride; with a small excess, mercuric chloride, sulphur dioxide, and sulphur dichloride; while, if the mercury is in excess, mercurous chloride, sulphur dioxide, and sulphur dichloride are formed; mercury and **sulphuryl chloride** in a sealed tube at 160° – 180° furnish mercuric chloride and sulphur dioxide. J. A. Besson found **thionyl bromide** forms mercury bromide, sulphur dioxide, and sulphur, while **thionyl chlorobromide** forms mercurous bromide, thionyl chloride, sulphur dioxide and sulphur. E. Divers and M. Shimose found **selenium dichloride**, Se_2Cl_2 , is decomposed by mercury. H. Moissan found that **phosphorous trifluoride** does not act on mercury at 350° . H. Goldschmidt found that mercury and **phosphoric chloride**, PCl_5 , furnish mercuric chloride and phosphorous chloride, PCl_3 . According to J. A. Besson, mercury decolorizes a soln. of **phosphorous iodide** in carbon disulphide, and mercury iodide is formed. B. Reinitzer and H. Goldschmidt heated an excess of mercury with **phosphoryl chloride**, $POCl_3$, for 15 hrs. at 290° , and obtained phosphorous chloride, phosphoric oxide, pyrophosphoryl chloride, $P_2O_3Cl_4$, crystals of mercurous oxide, and red mercury phosphide, while if the phosphoryl chloride be in excess, mercuric chloride and phosphate are formed. O. Ruff and co-workers found that **tungsten hexafluoride** attacks mercury, especially in the presence of hydrogen fluoride; **tungsten oxytetrafluoride**, WOF_4 , attacks

mercury only when warm, or in the presence of moisture. According to G. Meyer, the salt condenses on the surface of mercury immersed in a soln. of **alkali chloride**; but, according to I. Bhaduri, neither neutral nor alkaline soln. of alkali chlorides act on mercury. J. Müller observed the formation of sodium mercuric chloride when a soln. of sodium chloride is shaken with mercury. W. Palmaer observed that a soln. of potassium chloride or **potassium iodide** dissolves mercury in the presence of air. A. Ditte made a similar observation, and H. S. Hatfield found that the dissolution of mercury in an aq. soln. of mercuric and potassium iodides in the presence of air, is accelerated in sunlight if a trace of an iron salt be present. J. Shukoff found mercury is dissolved at the anode during the electrolysis of soln. of the **potassium bromide**, chloride, or iodide. According to C. Barfoed, and D. Vitali, an aq. soln. of **auric chloride** or **hydrochloroauric acid** absorbs mercury vapour and gold is produced; the reaction is very sensitive in the absence of nitric acid. A soln. of **platinic chloride** acts similarly. W. Wolters found **hypochlorous acid** attacks mercury, forming mercurous chloride, or, according to A. J. Balard, mercuric oxychloride, while, according to I. Bhaduri, **hypochlorites** form mercuric oxide. I. Bhaduri found that soln. of **alkali chlorates** have no action on mercury. A. Ditte stated that mercury is attacked by **iodic acid**.

According to R. von Schrötter,⁷ C. Brame, and M. Rosenfeld, when **sulphur** and mercury are heated together, the two elements unite to form mercury sulphide. Similar remarks apply to **selenium**. A. Baudrimont found that **sulphur chloride** converts mercury into mercurous and mercuric chlorides. U. Antony and G. Magri found liquid **hydrogen sulphide** has no action on mercury, and, according to M. Berthelot, hydrogen sulphide does not react with mercury at ordinary temp., nor at 100° if moisture be excluded; but if oxygen be also present, mercurous sulphide is formed at ordinary temp.—the presence of moisture retards the reaction. G. Reboul observed that the attack by hydrogen sulphide on the mercury meniscus is fastest where the curvature is greatest. J. Milbauer found that the presence of mercury does not stimulate the reaction between sulphur and hydrogen. M. Berthelot found that mercury very slowly decomposes **hydrogen selenide** with the formation of mercurous selenide—the reaction is not completed in three years at ordinary temp. W. Palmaer found that a soln. of **sodium sulphide** slowly dissolves mercury in the presence of air. O. Brunck found that **sodium hyposulphite** reacts with mercury, forming mercuric sulphide. According to M. Berthelot, mercury is not attacked by a cold aq. soln. of **sulphur dioxide** even after many days' action, alone, or in the presence of hydrochloric acid or dil. sulphuric acid. E. Divers and T. Shimidzu stated that mercury is not chemically attacked by **sulphur trioxide** provided moisture is rigorously excluded; the only phenomenon observable is the ready pulverization of the mercury after it has been shaken with the trioxide. C. M. van Deventer found that conc. **sulphuric acid** readily attacks mercury while the dil. acid has no action. Water-free **sulphuric acid** was found by M. Berthelot gradually to attack mercury, and if shaken at 20° for a couple of months, sulphur dioxide, mercuric sulphate, and a trace of mercuric sulphide are formed. A. Ditte said that only hot conc. sulphuric acid attacks mercury, forming sulphur dioxide, and J. R. Pitman, in opposition to C. Baskerville and F. C. Miller, found that conc. sulphuric acid at 25° does not attack moist or dry mercury, whether air be present or absent, and whether the acid be in excess or not. According to J. B. Hannay, hot conc. sulphuric acid forms a mixture of mercurous and mercuric sulphates, and if the mercury is completely dissolved, only mercuric sulphate is formed. He attributed the formation of mercurous sulphate to the reducing action of sulphur dioxide. C. Baskerville and F. C. Miller found that an excess of mercury with sulphuric acid of sp. gr. 1.84 forms sulphur dioxide and white crystalline mercurous sulphate, but at about 20° this compound is decomposed by the excess of acid. When a mixture containing an excess of acid is heated at 100° for 20 hrs., mercurous sulphate is obtained, and on heating at 150° for 2 hrs., a mixture of mercurous and mercuric sulphates is produced, containing 50 per cent. of

the former salt; as the temp. is raised, however, the amount of mercurous sulphate diminishes until, when mercury is added to the boiling acid, the product consists entirely of mercuric sulphate. When mercurous sulphate, or a mixture of this with mercuric sulphate, is heated with sulphuric acid, the amount of sulphur dioxide evolved is proportional to the quantity of mercurous salt present. No indication could be obtained of the liberation of hydrogen during the initial stages of the reaction, and no sulphide or free sulphur was produced. The acid is directly reduced by the metal, even at ordinary temp. No trace of hydrogen, sulphur, or sulphide was formed. The sulphuric acid does not act on mercury like it does on copper; and by the prolonged action of the acid, C. Baskerville obtained some mercurous sulphide. P. Braham stated that if the sulphuric acid contains a trace of nitric acid, mercurous hydrosulphate, HgHSO_4 , is formed after about a year's contact with mercury. J. Tafel has shown that no hydroxylamine is produced when nitric acid acts on mercury in the presence of sulphuric acid, and the reaction has been discussed by W. D. Bancroft. E. Sulkowsky found that dil. sulphuric acid attacks mercury in the presence of hydrogen peroxide. S. W. J. Smith studied the action of a mixture of sulphuric and hydrochloric acids. A. Sieverts and P. Lueg studied the retarding effect produced by alkaloids in the action of sulphuric acid on mercury.

G. Meyer found that with soln. of **sulphates** there is a condensation of the salt at the surface of the mercury. W. R. E. Hodgkinson and N. E. Bellairs found that fused **ammonium sulphate** acts less energetically on mercury than on copper; W. Smith attributed the action to the formation of ammonium hydrosulphate, NH_4HSO_4 . According to D. Borar, a hydrochloric acid soln. of **cupric sulphate** is reduced to cuprous chloride by mercury. E. Divers and T. Shimidzu found that when **pyrosulphuric acid** acts on mercury no effervescence occurs, provided the vessel is occasionally shaken to renew contact. As the action proceeds, mercurous sulphate slowly separates in the solid state. By using an acid containing much sulphur trioxide, the whole may become solid, and the action arrested in consequence. In any case, when the action has proceeded far, sulphur dioxide escapes freely from the liquid with slight effervescence. If the soln. of the mercury in the acid is poured into water, mercurous sulphate is precipitated, mixed with metallic mercury, and no sulphur dioxide is left. But the already solidified mercurous sulphate is not thus affected by contact with water. The dissolution of the mercury without evolution of gas is attributed to the great solubility of sulphur dioxide in fuming sulphuric acid, and the precipitation of mercury which occurs, when the fuming acid soln. of mercury is treated with water, is due to the action of sulphur dioxide on mercurous salts. According to N. Tarugi, **persulphates**, in acid, neutral, or alkaline soln., attack mercury—the potassium salt less tardily than the ammonium salt—and, according to M. G. Levi, E. Migliorini, and G. Ercolini, the mercury is covered by a yellow powder of mercuric oxide or basic sulphate. According to D. Borar, when a cold soln. of potassium persulphate is shaken with mercury, a slight black precipitate is first formed, and then a white precipitate which slowly changes to a lemon-yellow colour. The soln. acquires an acid reaction, and it contains potassium sulphate. With hot soln. a yellow precipitate is formed almost immediately. Mercuric sulphate readily gives the yellow basic sulphate when treated with water, while mercurous sulphate, even on boiling does not do so. The suggested reactions are symbolized: $2\text{K}_2\text{S}_2\text{O}_8 + 2\text{H}_2\text{O} = 4\text{KHSO}_4 + \text{O}_2$; $4\text{KHSO}_4 + \text{O}_2 + 2\text{Hg} = 2\text{K}_2\text{SO}_4 + 2\text{HgSO}_4 + 2\text{H}_2\text{O}$; and $2\text{HgSO}_4 + 3\text{H}_2\text{O} = \text{H}_2\text{SO}_4 + \text{HgSO}_4 \cdot \text{HgO} \cdot 2\text{H}_2\text{O}$. When mercury is heated with **selenic acid**, H_2SeO_4 , W. C. A. Cameron and E. W. Davy found a mixture of mercurous and mercuric selenite, but if the selenic acid be in excess, mercuric selenate is produced. According to M. E. Pozzi-Escot, a trace of **sodium tungstate** in conc. hydrochloric acid produced a blue coloration in the presence of mercury. A. Chilesotti found that the mercury cathode is not suitable for reducing **molybdates**.

According to F. Emich, a mixture of sulphuric acid and **sodium nitrite** reacts

with mercury, forming nitric oxide, and the velocity of the reaction is proportional to the surface presented by the mercury; while P. Sabatier found that when mercury is shaken with sulphuric acid and sodium nitrite, blue nitrosodisulphonic acid is formed. According to F. Raschig, **nitrososulphonic acid** or nitrosulphuric acid, ONO.HSO_3 or $\text{NO}_2.\text{HSO}_3$, in the presence of conc. sulphuric acid, is reduced by mercury to what he regards as blue nitrososulphonic acid, NO(OH).HSO_3 , or what E. Divers regards as nitroxysulphuric acid, $\text{HO.NO}_2:\text{N.HSO}_3$, and then to nitric oxide and sulphuric acid; E. Divers represents the reaction differently: $2\text{Hg} + \text{ONO.HSO}_3 + \text{NO.SO}_4 = \text{Hg}_2\text{SO}_4 + \text{HO.NO}_2:\text{N.HSO}_3$; and O. Wentzky interprets the reaction still another way. W. Manchot also noted the reduction, by mercury, of the blue-coloured **nitroxysulphuric acid**, $\text{HO.NO}_2:\text{N.HSO}_3$, produced in the manufacture of sulphuric acid.

F. H. Newman⁸ studied the effect of **nitrogen** on mercury as cathode in a discharge tube. Mercury can be agitated for a long time with nitrogen without change, and M. Berthelot could detect no reaction between the two elements. M. de Broglie found that nitrogen is ionized when bubbled through mercury. According to J. Stark, nitrogen is absorbed by mercury in a stream of canal rays. R. J. Strutt found activated nitrogen reacts with mercury, forming mercury nitride. W. Weyl, and E. C. Franklin and C. A. Kraus stated that mercury is not soluble in liquid **ammonia**, but W. Weyl found that sodio-ammonium and mercuric aminochloride react to form **mercury diammine**, $\text{Hg}(\text{NH}_3)_2$, as in the case of zinc ammine. C. Matignon and G. Desplantes found mercury is oxidized when shaken with aq. ammonia in the presence of oxygen. J. McKay found that when a soln. of **hydroxylamine** is electrolyzed with mercury electrodes, it forms ammonia. P. Sabatier and J. B. Senderens found that mercury is not perceptibly oxidized at 450° in **nitric oxide**; W. Ramsay found **nitrogen peroxide** to be decomposed by mercury; C. F. Gerhardt obtained mercuric nitrate and nitric oxide by passing nitrogen peroxide through cold mercury; and E. Divers and T. Shimidzu represented the reaction: $\text{Hg} + \text{N}_2\text{O}_4 = \text{HgNO}_3 + \text{NO}$, and showed that a little mercuric nitrate but no nitrite is formed. F. Russ found that nitrogen peroxide has no appreciable action on mercury at low temp. G. Reboul found that **nitrogen trioxide** attacks a meniscus of mercury fastest where the curvature is greatest.

E. Divers likened the action of **nitric acid** and **nitrous acid** on mercury to that of the same acids on copper—*q.v.* E. Abel found cold $0.3N\text{-HNO}_3$ has no perceptible action on mercury. According to N. A. E. Millon, purified nitric acid acts on mercury only when a reducing agent is present, and V. H. Veley, and E. Divers showed that nitric acid freed from nitrous acid does not attack mercury; and J. H. Stansbie found that the speed of the reaction is dependent on the proportion of nitrite which is present; and is decreased when the nitrite is converted to nitrate by boiling. W. Reuss obtained only mercurous nitrate by the action of dil. nitric acid on mercury in the cold, and also when heated on a water-bath provided the conc. of the nitric acid does not fall below 4 per cent. nor rise above 20 per cent. HNO_3 . According to P. C. Ray, when mercury is covered by a 10-cm. layer of nitric acid, of sp. gr. 1.11 at 15° , and at a temp. of $30^\circ\text{--}35^\circ$, bright yellow crystals of mercurous nitrite are freely formed. A part of the nitric acid is reduced to nitrous acid; some of the nitrite is decomposed by the nitric acid, and the proportion of nitrous acid in the soln. rapidly increases until mercurous nitrite and nitrate are accumulating in equi-molecular proportions; the proportion of nitrous acid in the soln. then remains constant and acts as a catalytic agent in the reaction between mercury and nitric acid: $2\text{Hg} + 2\text{HNO}_3 = \text{HgNO}_2 + \text{HgNO}_3 + \text{H}_2\text{O}$. He further assumes that when dil. nitric acid and mercury are left in contact for a long time, the following nine salts may form: (1) $\text{Hg}_2(\text{NO}_2)_2$; (2) $\text{Hg}_2(\text{NO}_3)_2$; (3) $\text{Hg}_2(\text{NO}_3)_2.2\text{H}_2\text{O}$; (4) $\text{HO.Hg}_2.\text{NO}_3$; (5) $\text{Hg}_2(\text{NO}_3)_2.\text{HO}(\text{NO}_3)\text{Hg}_2$; (6) $\text{Hg}_2(\text{NO}_3)_2.4\text{HO}(\text{NO}_3)\text{Hg}_2$; (7) $\text{HgO}.2\text{HO}(\text{NO}_3)\text{Hg}_2$; (8) $\text{HgO}.\text{HO}(\text{NO}_3)\text{Hg}.\text{HO}(\text{NO}_3)\text{Hg}_2$; and (9) $\text{Hg}(\text{NO}_3)_2$ aq.; not all of these salts have been isolated. According to C. Montemartini, mercury yields no ammonia with 27 and 50 per cent. nitric acid; the quantity of nitric

oxide produced diminishes as the conc. increases; 27.5 per cent. acid gives no nitrogen peroxide, but stronger acid yields large quantities just as in the cases of copper and bismuth. Mercurous nitrate is obtained in soln. on operating with 25 per cent. acid; more conc. acid (50–70 per cent.) gives the mercuric salt. T. Ericson-Aurén attributed the activity to action of local couples, with hydrogen as depolarizer.

J. J. Acworth found that in the presence of ammonium nitrate, nitrogen is the chief product of the reaction between mercury and nitric acid. N. A. E. Millon, V. H. Veley, and P. C. Ray showed that the presence of ferric sulphate or nitrate removes nitrous acid from nitric acid as fast as it is formed, and it thus inhibits the chemical change between nitric acid and the metals. P. C. Ray found that the reaction between mercury and nitric acid is accelerated by manganese or sodium nitrate, while the sulphates of manganese, sodium, and potassium neither accelerate nor retard the action. B. C. Banerji and N. R. Dhar found that while the presence of ferrous sulphate accelerates the action of nitric acid on mercury, the presence of ferric nitrate, sodium nitrate, manganous nitrate, potassium chlorate, or potassium permanganate retards the action. P. Ménière removed the vapour of mercury from air by passing the contaminated air through boiling nitric acid. W. Zorn obtained hyponitrites, hydroxylamine, and ammonia in the *electro-reduction of nitric acid* with a mercury cathode; and J. Tafel obtained an almost quantitative yield of hydroxylamine. W. J. Müller, with an amalgamated copper cathode, obtained nitrites and ammonia during the electro-reduction of soln. of **nitrates**. J. Shukoff obtained mercurous and mercuric salts in the proportions 120 : 1 in the electrolysis of a soln. of **potassium nitrate**. D. Borar observed no reaction between mercury and an aq. soln. of potassium nitrate. G. Meyer stated that with aq. soln. of the nitrates some of the salt condenses at the surface of the mercury. W. R. E. Hodgkinson and co-workers observed no reaction between mercury and aq. soln. of **ammonium nitrate**, but the molten salt was found to attack mercury less energetically than copper, the attack, according to W. Smith, is a result of the formation of nitric acid from the ammonium nitrate. W. R. E. Hodgkinson and A. H. Coote found that fused **ammonium nitrite** has no action on mercury.

The affinity between mercury and **phosphorus** appears to be small. According to O. Emmerling,⁹ and A. Granger, phosphorus vapour does not react with mercury vapour either at atm. press. or under press. in a sealed tube. A. Stock and F. Gomolka assume that phosphorus crystallizes from its soln. in molten mercury. D. Gernez found that molten phosphorus dissolves mercury, forming a colourless liquid which blackens on cooling owing to separation of mercury; the soln. clears again if re-heated. M. Blondlot found that mercury catalyzes the change from ordinary to black phosphorus. Mercury appears to form amalgams with **arsenic**, **antimony**, and **bismuth**, but the evidence in the case of arsenic and antimony is not so satisfactory. H. J. S. Sand and J. E. Hackford reduced solns. of **arsenates** and **arsenites** to arsenic, but not to arsine, by electrolysis between mercury electrodes. T. F. Rutter found that with the mercury cathode **vanadates** are reduced to vanadium sulphate, VSO_4 , in the presence of sulphuric acid.

O. Ruff and B. Bergdahl¹⁰ state that the solubility of **carbon** in mercury is very small. H. Erdmann and P. Köthner found that the metallic lustre of mercury is not altered by heating it with **acetylene**, but at the distillation temp. of mercury, a very small grey sublimate is formed which gives a scarcely perceptible trace of acetylene when treated with water. M. Berthelot stated that when mercury is heated to 550° in a sealed tube with **carbon monoxide**, the weight of the mercury increases a little, no free carbon can be detected, but a trace of carbon dioxide is formed. The prolonged shaking of mercury with **carbon dioxide** gives no perceptible sign of any chemical change; but with a prolonged sparking, T. de Saussure found that some mercuric oxide is formed. M. Berthelot found that cyanogen does not unite with mercury when heated in a sealed tube at 200° or 300°; the gas does not appear to be absorbed by the mercury, but the latter is covered with a brown film,

E. Obach found that purified **carbon disulphide** as well as that containing hydrogen sulphide as impurity, acts on mercury in the presence of air. According to M. Berthelot, when a mixture of nitrogen and carbon disulphide confined over mercury is sparked, or exposed to the silent discharge, mercuric thiocyanate, $\text{Hg}(\text{SCy})_2$, is formed. H. Moissan noted that **ethylene tetraiodide** acts slowly on cold mercury. G. Tammann found mercury vapour reacts with **carbon tetrachloride** at $600^\circ\text{--}700^\circ$ producing a dense form of carbon and mercurous chloride. The reaction starts at 400° when the press. is $900\text{--}2760$ atm. Analogous results were obtained with **carbon tetrabromide**, and **carbon tetraiodide**—*vide* sodium amalgam. According to L. Elsner, mercury is insoluble in an aq. soln. of **potassium cyanide**; but W. Palmaer found it to be slowly soluble with access of air; and G. A. Goyder observed a marked solubility without the evolution of gas in a 6 per cent. soln. of that salt. A. Brochet and J. Petit found that the alternating current electrolysis of a soln. of potassium cyanide with mercury electrodes yields no double salt; but B. Renault found some mercury dissolves at the anode during the direct current electrolysis of the soln. G. McP. Smith found a soln. of **potassium ferricyanide** dissolves mercury best in the presence of potassium hydroxide, and he represents the reaction: $16\text{K}_3\text{FeCy}_6 + 6\text{Hg} = 6\text{K}_2\text{HgCy}_4 + \text{Fe}_4(\text{FeCy}_6)_3 + 9\text{K}_4\text{FeCy}_6$; or with potassium hydroxide: $\text{Fe}_4(\text{FeCy}_6)_3 + 4\text{Fe}(\text{OH})_3$. G. Meyer found that potassium ferricyanide is reduced by mercury to the ferrocyanide. A. Brochet and J. Petit did not succeed in electrolyzing a soln. of **potassium ferrocyanide** with mercury electrodes.

According to A. Christoff, mercury does not dissolve in **alcohol**, **benzene**, or **nitrobenzene**, although the vapour can diffuse at ordinary temp. through these liquids. H. C. Bolton found that mercury dissolves in a mixture of **citric acid** and sodium nitrate; and J. H. Mathews, that **trichloroacetic acid** in nitrobenzene soln. does not attack mercury. C. B. Gates studied the displacement of copper by mercury from soln. of salts of the organic acid in various organic solvents. Mercury acts as a catalytic agent in the reduction of some organic compounds—*e.g.* D. Borar found that a little nitrobenzene is reduced to aniline in the presence of mercury and hydrochloric acid; several organic compounds are reduced electrolytically with a mercury cathode; and many organic sulphides act on mercury. According to D. B. Dott, purified **ether** has no action on mercury, but ether containing peroxide impurities produces a dark film, and a grey powder; and if much peroxide is present, some yellow mercuric oxide.

Mercury was found by C. Winkler¹¹ not to unite with **silicon**, even if the two elements are heated for a day at 300° . F. Grandjean found mercury is absorbed by some **zeolites**—*e.g.* **levyne** and **chabasite**, but not by **gmelinite**. E. Warburg observed in the electrolysis of **glass** between mercury electrodes—not with electrodes of sodium amalgam—the formation of a badly conducting layer. G. Schulze noted the diffusion of mercury in the glass. V. Meyer found that in the distillation of impure mercury, glass retorts are soon destroyed, but not so porcelain retorts. According to H. Moissan, **boron phosphide**, BP, does not act on mercury; **boron trisulphide** has no action on mercury, but **boron pentasulphide** is reduced to the trisulphide; **boron phosphoiodides**— BPI_2 at 100° , and BPI in carbon disulphide soln.—are reduced to the phosphide, BP. According to O. Mohr, and E. von Pickardt and W. Angermann, vessels of **aluminium** are rapidly attacked by mercury. A. Holt found that sodium hydride is not affected by mercury. A. Matthiessen and C. Vogt stated that mercury does not dissolve **mercuric oxide**, but C. Barfoed found that by trituration mercury can form a salve-like mixture with **mercurous oxide** and **mercurous iodide**, and that the oxides of other heavy metals, like **lead oxide**, behave in a similar way. H. Rose stated that mercury precipitates metal oxides from many **metal salt** soln., and A. Mailhe added that basic salts are also precipitated. D. Borar found that **ferric salts** in the presence of hydrochloric acid are not reduced by mercury. P. Schafhäütt found that mercury reduces aq. soln. of ferric chloride, forming mercurous and ferrous chlorides; the action is faster in the presence of hydrochloric acid. The observation was verified by D. J. Carnegie,

and L. W. McCay and W. T. Anderson. According to D. Borar, **potassium dichromate** is reduced under these conditions: $\text{K}_2\text{Cr}_2\text{O}_7 + 6\text{Hg} + 14\text{HCl} = 6\text{HgCl} + 2\text{CrCl}_3 + 2\text{KCl} + 7\text{H}_2\text{O}$; he also represented the reduction of **potassium permanganate** by mercury: $2\text{KMnO}_4 + 3\text{Hg} + \text{H}_2\text{O} = 3\text{HgO} + 2\text{MnO}_2 + 2\text{KOH}$; and W. Kirchmann stated that the reduction in the cold gives mercurous oxide, and when heated, mercuric oxide. Aq. soln. of alkali permanganates and mercury were found by A. Gawalowsky to form gradually a deep violet compound, and, in the presence of potassium hydroxide, a double manganate is formed together with a black substance, possibly mercurous manganate. F. Streintz found that at 100° , the vapour of mercury forms a mirror-like coating on the faces of crystals of **argentite**, or silver glance, Ag_2S , and some cinnabar, HgS , is simultaneously formed. The action of mercury on the metals is discussed in connection with the respective amalgams. A. Feodoroff found that when mercury is heated in an hermetically sealed **iron** tube, the latter is permeable to the former at 600° – 620° . A sq. metre of surface of mercury was found by H. von Euler to absorb 0.004 mgrm. of ions from a soln. of **mercuric chloride**.

Reactions of analytical interest.—There are two series of mercury salts—mercurous salts, and mercuric salts. In general, heat and light transform mercurous salts—nitrate, chloride, phosphate, acetate, sulphate, etc.—into mercuric salts and mercury, while the reverse change may occur at lower temp. **Hydrochloric acid** and **soluble chlorides** give no precipitate with mercuric salts of moderate conc., but with mercurous salts, a white precipitate of mercurous chloride is formed, which is insoluble in water and dil. acids, but soluble in conc. nitric acid or in aqua regia, and in chlorine or bromine water, $2\text{HgCl} + \text{Br}_2 = \text{HgCl}_2 + \text{HgBr}_2$. If the soln. of the mercurous salt is conc. the precipitate is curdy, if dil. the precipitate is pulverulent, and if very dil., a white opalescence is produced which, according to C. H. Pfaff,¹² is visible with soln. containing one part of mercurous nitrate in 100,000 parts of water; C. R. Fresenius said 1 in 327,000; and F. Jackson, 1 in 16,000 with hydrochloric acid and 1 in 15,000 with sodium chloride soln. When mercurous chloride is boiled for a long time with water, it becomes grey owing to its partial decomposition into mercury and mercuric chloride, and when boiled with sulphuric acid, sulphur dioxide is evolved: $2\text{HgCl} + \text{H}_2\text{SO}_4 = 2\text{HCl} + \text{Hg}_2\text{SO}_4$, followed by $\text{Hg}_2\text{SO}_4 + 2\text{H}_2\text{SO}_4 = 2\text{H}_2\text{O} + 2\text{HgSO}_4 + \text{SO}_2$. Mercurous chloride is blackened by alkali hydroxide, and by aqua ammonia; and it is slowly dissolved by cold soln. of ferric salts, chromic acid, and permanganic acid, forming mercuric salts. **Hydrobromic acid** and **soluble bromides** also give white precipitates with mercurous salts. Mercurous salts give an olive-green precipitate of mercurous iodide when treated with a soln. of **potassium iodide**; the precipitate is soluble in an excess, forming mercuric potassium iodide, K_2HgI_4 , and mercury. Mercuric salts give a red precipitate of mercuric iodide which is soluble in an excess, forming the double salt, K_2HgI_4 —cadmium salts behave similarly. According to F. Jackson, one part of a mercurous salt in 8000 can be detected and one part of a mercuric salt in 2000; for the latter, T. G. Wormley gave 1 : 3380, and P. Jannasch 1 : 1500.

When soln. of mercuric salts are treated with **hydrogen sulphide**, a white precipitate of mercuric thiochloride, $\text{HgCl}_2 \cdot 2\text{HgS}$, is first formed; this is coloured yellow, brown, and finally black by the prolonged action of hydrogen sulphide. According to R. Palm, a soln. of mercuric cyanide does not give these intermediate compounds, but the black sulphide is precipitated directly. A. Kekulé found that hydrogen sulphide does not precipitate the sulphide from soln. of mercuric iodide in hydriodic acid, and similar remarks apply to soln. of mercuric bromide in hydrobromic acid. R. Rupp found that the mercury is slowly precipitated from a soln. of mercuric salicylate. According to J. L. Lassaigne, one part of mercuric salt can be detected in 23,000 parts of soln.; T. G. Wormley said 1 in 6770; and F. Jackson, 1 in 16,000. The sensitiveness of the reaction has also been examined by F. C. Schneider, B. Neumann, and by L. Vignon. Black mercuric sulphide is insoluble in boiling dil. acids. It dissolves in conc. hydrochloric acid. Hot conc. nitric acid gradually changes it

into white thionitrate, $\text{Hg}(\text{NO}_3)_2 \cdot 2\text{HgS}$, and by a longer action, soluble mercuric nitrate is produced. The sulphide dissolves readily in aqua regia with the separation of sulphur; it is insoluble in soln. of potassium or sodium hydroxide, and ammonium sulphide, but, unlike the sulphides of silver, lead, bismuth, and copper, it dissolves readily in soln. of the alkali sulphide—not, according to C. Barfoed, hydrosulphide—forming, say, $\text{Hg}(\text{SK})_2$, which is readily hydrolyzed by water: $\text{Hg}(\text{SK})_2 + \text{H}_2\text{O} \rightleftharpoons \text{KOH} + \text{KSH} + \text{HgS}$, so that a large excess of the alkali sulphide is needed for the soln. Unlike the sulphides of silver, lead, bismuth, copper, and cadmium, mercuric sulphide dissolves in potassium thiocarbonate soln., and from the soln. it is precipitated by carbon dioxide. According to K. Bülow, in the presence of zinc or cadmium sulphide, a soln. of sodium sulphide converts mercuric sulphide into a double sulphide; while, according to T. Willm, mercuric sulphide is perceptibly soluble in ammonium sulphide in the presence of stannic sulphide. With mercurous salts, hydrogen sulphide precipitates immediately a black mixture of mercuric sulphide and mercury; the latter remains undissolved when the precipitate is treated with potassium sulphide, but it all dissolves in an alkali polysulphide. J. L. Lassaigne found that one part of mercurous salt in 46,000 parts of soln. can be detected by hydrogen sulphide. J. Haidlen and C. R. Fresenius found that hydrogen sulphide gives a precipitate with mercuric salts in the presence of potassium cyanide; and C. J. Pretzfeld, in the presence of tartaric acid. According to J. W. Slater, a soln. of **sodium sulphide**, or of **ammonium sulphide**, behaves like hydrogen sulphide.

According to J. F. John, and H. Rose, a soln. of **potassium hydroxide** precipitates black mercurous oxide, Hg_2O , mixed with some mercuric oxide and mercury, from soln. of mercurous salts; and from mercuric salts, yellow mercuric oxide. If insufficient alkali is added for complete precipitation, a reddish-brown basic salt, say, $\text{HgO} \cdot \text{HgCl}_2$, or $2\text{HgO} \cdot \text{HgCl}_2$, is formed, and, in the presence of ammonium salts, the so-called white precipitate, say, $\text{NH}_2 \cdot \text{Hg} \cdot \text{O} \cdot \text{Hg} \cdot \text{NO}_3$, is formed. Mercuric oxide and the basic salts are readily soluble in acids; but not in an excess of the precipitant. J. Spiller found that in the presence of citric acid no precipitation occurs; but C. Aubel and G. Ramdohr found that tartaric acid does not prevent the precipitation. F. Jackson found one part of mercuric salt in 500 parts of water could be detected by sodium hydroxide; T. G. Wormley said 1 : 677. Aq. **ammonia** with mercurous nitrate gives a black mixture of mercury and a mercuric amido-salt, say, $\text{NH}_2 \cdot \text{Hg} \cdot \text{O} \cdot \text{Hg} \cdot \text{NO}_3$; with mercurous chloride, a mixture of mercury and mercuric amidochloride, $\text{Cl} \cdot \text{Hg} \cdot \text{NH}_2$, is formed. When the black precipitate is boiled with dil. hydrochloric acid, or a conc. soln. of ammonium chloride, the amide passes into soln. and the mercury remains undissolved. N. T. de Saussure, and C. H. Pfaff stated that 0·000006 part of ammonia in one part of water gives a sensible coloration with mercurous nitrate. The reaction has also been discussed by H. Hager. Aq. ammonia gives with mercuric chloride a white precipitate, $\text{Cl} \cdot \text{Hg} \cdot \text{NH}_2$, the so-called infusible white precipitate; this precipitate is soluble in acids, and in hot ammonium chloride, forming a fusible white precipitate, $\text{Hg}(\text{NH}_2\text{Cl})_2$. When aq. ammonia is allowed to act on mercuric nitrate, the white compound, $\text{NH}_2 \cdot \text{Hg} \cdot \text{O} \cdot \text{Hg} \cdot \text{NO}_3$, is formed which is easily soluble in ammonia in the presence of ammonium nitrate. T. G. Wormley found that one part of mercuric salt in 13,500 parts of water can be detected by the ammonia reaction; and F. Jackson, one part of mercurous or mercuric salt in 80,000 of soln. Soln. of mercuric chloride or nitrate give a reddish-brown precipitate of a basic carbonate, $3\text{HgO} \cdot \text{HgCO}_3$, when treated in the cold with **alkali carbonate**; when boiled, yellow mercuric oxide is formed. Alkali carbonates with mercurous salts precipitate yellow mercurous carbonate which quickly becomes grey owing to the decomposition: $\text{Hg}_2\text{CO}_3 = \text{HgO} + \text{Hg} + \text{CO}_2$. Similar results are obtained with **ammonium carbonate** as are obtained with aq. ammonia. F. Jackson found the sensitiveness of the reaction with sodium carbonate to be 1 : 1600 with mercurous salts, and 1 : 250 with mercuric salts. According to H. Demarçay, cold soln. of mercurous or mercuric salts are precipitated by

magnesium, barium, strontium, or calcium carbonate. A soln. of mercuric chloride gives no precipitate with **alkali hydrocarbonates**, but a reddish-brown basic carbonate is obtained with soln. of mercuric nitrate. A soln. of **potassium cyanide** gives no precipitate with a soln. of mercuric chloride because both the cyanide and chloride readily form soluble complexes with alkali chloride or cyanide. Mercuric nitrate gives a white precipitate of mercuric cyanide which is soluble in an excess of water or of potassium cyanide. A soln. of potassium cyanide gives a mixed precipitate of mercury and mercuric cyanide when added to a soln. of mercurous nitrate. Mercuric nitrate soln. with **potassium thiocyanate** precipitate white mercuric thiocyanate soluble in an excess of either reagent; mercurous salts give a mixture of mercury and mercuric thiocyanate. Soln. of mercurous salts give a black precipitate of the sulphide when treated with **sodium thiosulphate**; and with mercuric salts, H. Rose obtained a white precipitate which redissolves in an excess of thiosulphate; the white precipitate slowly becomes yellow, and then brown; in a boiling feebly acid soln., the yellowish-orange precipitate rapidly forms black mercuric sulphide. Mercurous salts with **potassium ferrocyanide** give a white precipitate; mercuric salts also give a white precipitate, if not too dil., and the colour turns blue on standing for some time. Mercurous salts with **potassium ferricyanide** give a yellowish-green precipitate which becomes white on standing; and with mercuric salts a green precipitate. Mercurous salts give a white precipitate of mercurous phosphate when treated with **sodium phosphate**, sensitive, according to C. H. Pfaff, to 1 : 10,000; with mercuric salts, white mercuric phosphate is similarly precipitated, and the reaction, according to C. H. Pfaff, is sensitive to 1 : 500.

Not too dil. soln. of mercurous salts give a white precipitate of mercurous sulphate, Hg_2SO_4 , when treated with **sulphuric acid** or a **soluble sulphate**; the precipitate is sparingly soluble in cold water, decomposed by boiling water, soluble in nitric acid, and blackened by alkalies. According to T. G. Wormley, the reaction is sensitive to 1 : 1000. Mercuric salts give no precipitate with sulphuric acid or soluble phosphates. Mercurous nitrate soln. gives a red precipitate of mercurous chromate when heated with a neutral soln. of **potassium chromate**; with mercuric salts, yellow mercuric chromate is precipitated, and this precipitate becomes red when mixed with water and allowed to stand for a long time, or boiled. F. Jackson found the sensitiveness of the reaction to be 1 : 4000 with mercurous salts, and 1 : 333 with mercuric salts. Mercuric nitrate soln. give a yellowish-brown precipitate with **alkali dichromate**, but not so with a mercuric chloride soln.; with mercurous salts, the red chromate is precipitated. A boiling soln. of **ferrous sulphate** reduces mercuric nitrate to the metal, but mercuric chloride or cyanide is not reduced; with mercurous salts, white mercurous sulphate is precipitated, and this, especially when heated, is reduced to the metal—not so with the mercurous halides. A soln. of **stannous chloride** reduces mercuric chloride first to insoluble mercurous chloride, and the latter in turn to the metal. If the grey powdered mercury be decanted from the soln., and boiled with dil. hydrochloric acid, globules of mercury are formed. F. Jackson found the sensitiveness of the reaction with stannous chloride to be one part of mercuric salt in 32,000 parts of soln., or one part of mercurous salt in 16,000 parts of soln., or, according to T. G. Wormley, 1 : 13,500. The metals **aluminium, copper, zinc, and iron** reduce mercurous and mercuric salts to mercury. C. Reichard gave the sensitiveness of the aluminium precipitation as 1 : 130,000; soln. of mercurous salts with **oxalic acid**, or **alkali oxalates** give a white precipitate of mercurous oxalate, $\text{Hg}_2\text{C}_2\text{O}_4$, sensitive, according to C. H. Pfaff, to 1 : 10,000; mercuric salts, excepting the chloride, also give a white precipitate, HgC_2O_4 . According to P. Cazeneuve, mercurous and mercuric salts in alcoholic soln. give a bluish-violet coloration with **diphenylcarbazine**; the presence of copper masks the reaction, and the presence of zinc acts as an inhibitor. P. Mènière found the reaction sensitive to 1 : 5,000,000. According to G. Déniges, **zinc purpurate** gives a peach-coloured precipitate with a soln. containing 0.4 mgrm. of mercury per c.c. Silver salts give a violet precipitate.

The uses of mercury.—Mercury is used in the amalgamation processes for the extraction of gold and silver; as an electrode in the preparation of normal cells, and in electroanalyses; in thermometers, barometers, and other physical and electrical apparatus. It is used in the preparation of mirrors.¹³ Mercury arc lamps are used for illumination, and as a source of ultra-violet light. The salts are used as antiseptics, and in medicinal preparations; in photography; in the preparation of colours—e.g. vermilion; in organic syntheses, and in general chemical operations. The recovery of mercury from mercurous sulphate residues has been discussed by M. Lemire.

§ 5. The Atomic Weight and Valency of Mercury

The ratios of the two sp. hts., and the vapour density of mercury vapour, previously discussed agree with the assumption that the mol. is monatomic, and I. Traube¹ cited evidence that the element has the same **molecular weight** in the liquid and gaseous states; and he found the **atomic solution volume** of 200.4 parts of mercury is the same as that of one part of hydrogen. The sp. ht. and heat of vaporization were found by M. Langlois to agree with the assumption that the mol. is monatomic. The effect of temp. on the sp. ht. led L. Sohncke and the sp. gr. before and after melting led C. A. Seyler to the same assumption. W. Broniewsky observed no signs of molecular association when mercury is cooled to -183° . J. Stark suggested that liquid mercury may have polyatomic molecules because the liquid is a good electrical conductor, while the vapour is an insulator. C. Liebenow also assumed from a comparison of the electrical conductivity of the metal and its amalgams that the molecule of liquid mercury is polyatomic. D. Strömholm found the rise of the b.p. of mercury chloride in ethereal soln. agrees with a mol. wt. of 277—theory for HgCl_2 requires 271. F. M. Raoult, J. J. van Laar, and G. Tamman, from the f.p. of amalgams assumed that the mol. is polyatomic; and R. Cenac inferred from Eötvös' rule that the molecule of liquid mercury is probably triatomic. A. Avogadro supposed that the mercury molecule is diatomic, and in that case, J. B. A. Dumas' value for the vapour density of mercury would make the mol. wt. of mercury 200, and the at. wt. 100, and the accepted formula HgO for mercuric oxide would have to be changed to Hg_2O . Independent evidence obtained by studying the chemical transformations of the mercuric compounds favours the formula HgO , and the assumption that the mol. of mercury vapour is monatomic. A. Kundt and E. Warburg's work on the sp. ht. of mercury vapour gives a value in harmony with M. A. Gaudin's early assumption that the molecule is monatomic.

The **valency** of mercury in mercurous salts is like that of silver, and in mercuric salts like that of zinc and cadmium. The hydrogen eq. of the former is 200, that of the latter, 100. J. Stark and co-workers state that the spectral lines 365.0 and 365.5 are produced by bivalent mercury ions, and the line 253.6, by univalent mercury ions. E. Abel, A. Ogg, and E. Bose believe that in aq. soln. mercurous ions are bivalent; W. Bolton obtained evidence of the formation of univalent ions in the electrolysis of soln. of mercuric halides in the alkali halides. J. von Kowalsky observed that mercury vapour in a high vacuum ionizes in two stages. J. J. Thomson observed in his positive ray analysis tube that the mercury atom may carry

1 to 7 and probably 8 electrostatic charges. E. Abel found the tendency of electrically neutral ions to pass into mercurous ions is greater than with the nobler mercuric ions. K. A. Hofmann and E. C. Marburg discussed the tendency of mercury to form atomic complexes; and H. Ley and H. Kissel, the tendency to form Hg_2C - and Hg_2N -complexes.

J. J. Berzelius² represented mercurous and mercuric oxides respectively by the formulæ HgO and HgO_2 on the assumption that if the atomic weight of oxygen is 16, that of mercury is 400, but in 1826 he altered this to 200, making the formulæ the same as those employed at the present day. L. Gmelin represented the eq. wt. of mercury by 100, and the two oxides respectively Hg_2O and HgO . The value 200 for the at. wt. of mercury is supported by the inference from (1) Avogadro's rule applied to the vapour density, and the mol. wt. of the compounds in soln.; (2) Dulong and Petit's rule; (3) Mitscherlich's rule and the isomorphism of mercuric, lead, and cupric compounds; and (4) the position of mercury in the periodic table. The latter has been discussed by A. J. Hopkins, R. Lorenz, F. Sanford, E. W. Wetherell, P. C. Ray, C. Zenghelis, G. Tammann, A. Smits and H. L. de Leeuw, etc.

In 1818, N. G. Sefström³ determined the at. wt. of mercury by oxidizing the heated metal, and obtained the value 200.9. In 1833, E. Turner decomposed mercuric oxide, and thus obtained the ratio $\text{HgO} : \text{Hg}$, from which the at. wt. is 200.6; O. L. Erdmann and R. F. Marchand, in 1844, obtained from the same ratio, 200.10; G. B. Taylor and G. A. Hulett reduced mercuric oxide with iron, and obtained 200.37 \pm 0.024; and in 1896, W. L. Hardin evaluated the ratio $\text{HgO} : \text{Hg}$ by the electrodeposition of mercury from a soln. of the oxide in a soln. of potassium cyanide, and he obtained 200.19. O. L. Erdmann and R. F. Marchand distilled the sulphide with copper, and from the ratio $\text{HgS} : \text{Hg}$ obtained 200.54 for the at. wt. of mercury. E. Turner analyzed the chloride, and from the ratio $\text{HgCl}_2 : 2\text{AgCl}$ he calculated the at. wt. 202.05; and from the ratio $\text{HgCl} : \text{AgCl}$, 200.6. E. Turner also evaluated the ratio $\text{HgCl}_2 : \text{Hg}$, by reducing mercuric chloride with stannous chloride, and obtained 199.6; L. F. Svanberg distilled mercuric chloride with lime, and from the ratio $\text{HgCl}_2 : \text{Hg}$ obtained 199.59; N. A. E. Millon by a similar method obtained 200.21; and W. L. Hardin, from the electrolysis of soln. of silver chloride, bromide, and cyanide in potassium cyanide, obtained from $\text{HgCl}_2 : \text{Hg}$, 200.04; $\text{HgBr}_2 : \text{Hg}$, 199.89; and $\text{HgCy}_2 : \text{Hg}$, 199.99. C. W. Easley reduced mercuric chloride with hydrogen peroxide, and obtained 200.478; and by reducing the bromide, C. W. Easley and B. F. Braun obtained 200.64. W. L. Hardin also determined the electrochemical eq. of mercury in terms of silver, and from the ratio $\text{Hg} : 2\text{Ag}$ obtained 200.02. G. Hinrichs, F. W. Clarke, and B. Brauner have attempted to deduce the best representative value for the at. wt. of mercury from these determinations. The value 200.6 is given in the International Table of Atomic Weights for 1921. A. L. Bernoulli calculated 200.817 from the kinetic theory. The **atomic number** is 80.

With the positive ray analysis, F. W. Aston found that mercury has about six isotopes with at. wt. 202 and 204, and three or four with at. wt. ranging from 197 to 200. J. H. J. Poole considered the possibility of separating isotopes by centrifuging the liquid at 60,000 rev. per min., when the difference in sp. gr. of the isotopes is 1.5 per 1000, and J. N. Brönsted and G. Hevesy say that a partial separation of the isotopes of mercury was obtained by evaporating mercury at a low press., and condensing the evaporated atoms on a cooled surface—the density of the condensed mercury was 0.999980, and of the residual mercury 1.000031 (mercury unity) when the experimental error was less than one in a million. They also found that when mercury vapour penetrates through narrow openings into a condensation space, the lighter isotope is found in a relatively larger amount than in ordinary mercury. The subject has been also discussed by R. S. Mulliken and W. D. Harkins, W. D. Harkins and S. L. Madorsky, R. S. Mulliken, and W. Jäger and H. von Steinwehr. J. N. Brönsted and G. Hevesy found no measurable difference in the at. wt.

of mercury from different geological and geographical sources, and this makes it probable that the isotopic composition of mercury of terrestrial origin is the same.

§ 6. Mercurous Oxide

Mercury forms at least two series of compounds in which the mercury behaves as if it were two different elements, for the reactions of the series are quite different. In the mercurous salts the mercury behaves like a univalent element, and in the mercuric salts like a bivalent element. According to H. Kopp,¹ attention was first directed to the lower oxide from the observation that soln. of mercury in nitric acid are different when prepared hot and cold. N. Lemery, for example, showed that the soln. gives different results when treated with salt, and T. Bergman, that the reactions of the two soln. differ in many other respects. It was assumed that more phlogiston was lost when the mercury dissolved in the hot acid than when in the cold acid; and this hypothesis, expressed in terms of Lavoisier's oxidation theory, means that in the one mode of preparation the mercury is in a higher state of oxidation than in the other.

The lower oxide of mercury is called *black oxide of mercury*, and also **mercurous oxide**, Hg_2O . P. Moscati,² and G. Moretti obtained it by decomposing a mercurous salt with an aq. soln. of an alkali hydroxide, and washing and drying the product in the dark. M. Donovan treated finely divided mercurous chloride, suspended

in water, with an excess of the alkali; if too little alkali be employed, a basic mercurous chloride is formed, and then oxidized to a basic mercuric chloride, and a further addition of alkali produces a mixture of mercury, mercurous and mercuric oxides. A. Duflos poured a soln. of mercurous nitrate into an alcoholic soln. of potassium hydroxide, and washed and dried the product as before. The product dried over sulphuric acid was found by L. Schaffner to contain no water; but N. J. B. G. Guibourt has stated that it is impossible to obtain pure mercurous oxide because, during the washing, even in the dark, it is resolved into a mixture of mercuric oxide and mercury; J. Lefort also found that the mercurous oxide obtained by precipitation with alkali hydroxide contains mercuric oxide and mercury because it amalgamates gold leaf.

The brownish-black powder has no taste or smell. A sample prepared by C. J. B. Karsten from mercurous chloride and potassium hydroxide had a **specific gravity** 8.9503, and one likewise prepared by W. Herapath, a sp. gr. 10.69—presumably one sample had more free mercury than the other. Analyses were made by N. G. Sefström, M. Donovan, A. F. de Fourcroy and L. J. Thénard, M. Zaboada, N. J. B. G. Guibourt, M. Braamcamp and S. Oliva, etc. The **action of pressure** is to decompose mercurous oxide. F. Streintz found that oxygen is given off when it is compressed between 10,000 and 13,000 atm. The **action of heat** is to decompose mercurous oxide into mercury and mercuric oxide; according to M. Donovan, the reaction takes place at 100°, but A. Vogel obtained no decomposition at this temp. T. Graham, and W. Bruns and O. F. von der Pfordten found the dry powder is decomposed at 100° into mercury and mercuric oxide, and A. F. de Fourcroy and L. J. Thénard, and S. Hada stated that the change occurs slowly at ordinary temp. S. Hada found that mercurous oxide increases in weight when exposed to air. Oxygen is evolved when mercurous oxide is heated to redness. The **action of light** is to resolve mercurous oxide into mercury and mercuric oxide, and, according to G. Suckow, also under a layer of water. M. Berthelot exposed to sunlight some mercurous oxide in an evacuated sealed tube; after a month, some quicksilver had been formed. J. Thomsen gave for the **heat of formation** ($2\text{Hg}, \text{O}$) = 42.2 Cals.; R. Varet, ($2\text{Hg}_{\text{liq.}}, \text{O}$) = 22.2 Cals.; and ($\text{HgO}_{\text{solid}}, \text{Hg}_{\text{liq.}}$) = 0.7 Cal. W. Nernst gave ($2\text{Hg}, \text{O}$) = 22 Cals. M. de K. Thompson gave —13,400 cals. for the **free energy of formation**, and —22,200 cals. for the **total energy**. N. R. Campbell found that the **radioactivity** of mercurous oxide is very small. G. A. Dima observed a **photoelectric effect**. J. Gibson found the electrical conductivity increased by exposure to light. F. Streintz noted that the compressed powder at 80° has about one-fourth the **electric resistance** it possesses at ordinary temp. A. J. Allmand noted that the **electromotive force** of mercurous oxide is irregular owing to the tendency to form mercuric oxide.

According to J. W. Fay and A. F. Seeker, mercurous oxide is reduced by **hydrogen** at 80°; but, according to A. Colson, no reduction occurred when heated with hydrogen at 100° for four days, and **oxygen** is rapidly absorbed by mercurous oxide at 100°. C. T. Barfoed, and S. Hada showed that mercurous oxide both oxidizes and dissociates at ordinary temp.; when exposed to air it may increase or decrease in weight according to the conditions—in the closed atm. of moist air it increases in weight, for dissociation is checked and oxidation favoured; but if a large surface is exposed to the open air, it loses in weight, for then dissociation and volatilization of mercury proceed faster than the oxidation of the undecomposed mercuric oxide. M. Rosenfeld showed that when heated in a current of air, the black oxide is produced at 215°, and the red oxide at a higher temp.; the oxidation of mercurous oxide is accelerated if a trace of potassium is present. I. Bhaduri found mercurous oxide to be almost insoluble in cold **water**, but one part of the oxide dissolves in 150,000 parts of warm water. A. von Antropoff observed that **hydrogen peroxide** reacts with explosive violence. The black film which forms on mercury during the pulsating catalytic decomposition of hydrogen peroxide is believed by A. von Antropoff to be *mercurous peroxide* or **mercurous dioxide**, Hg_2O_2 , but it decomposes

so easily that it has not been isolated. A. Duflos found the oxide prepared by his process gives up nothing to dil. **hydrochloric acid**. According to J. B. Berthemot, when mercurous oxide is boiled with a soln. of **potassium iodide**, it furnishes mercury and potassium mercuric iodide, while if the mercuric oxide be in excess, mercurous iodide is also formed. J. S. F. Pagenstecher, and L. Thompson found that a conc. soln. of **ammonium chloride** decomposes mercurous oxide with the evolution of ammonia and the formation of mercury and mercuric chloride. According to A. J. Allmand, the **solubility product** $[\text{Hg}_2''][\text{OH}']^2$ is 4.8×10^{-24} . H. Rose found mercurous oxide is decomposed by water, forming mercuric oxide and mercury. K. Brückner found that when tritreated dry with **iodine**, and gently heated, mercuric iodide and iodate are formed; the reaction also proceeds slowly in contact with water, or alcohol. J. B. Senderens found that a mixture of **sulphur** and mercurous oxide is inflamed by friction, and sulphur dioxide, mercuric sulphate and sulphide are formed; the reaction with sulphur also occurs under boiling water. According to E. C. Franklin and C. A. Kraus, mercurous oxide is insoluble in liquid **ammonia**. H. Rose found mercurous oxide is decomposed by a soln. of **ammonium nitrate** with the separation of mercury. A mixture of **phosphorus** and mercuric oxide detonates when struck. T. Graham observed that mercurous oxide absorbs that "peculiar principle" which makes **phosphine** spontaneously inflammable, and is slowly decomposed by the gas itself. M. Braamcamp and S. Oliva found **phosphorous acid** reduces mercurous oxide to the metal. C. Reichard found an aq. soln. of **arsenious oxide** has scarcely any action, but the oxide is reduced by alkali or ammonium arsenite. J. W. Fay and A. F. Seeker observed the reduction of mercurous oxide by **carbon monoxide** at 0° . According to G. C. Wittstein, a soln. of **ammonium carbonate** decomposes mercurous oxide into mercuric oxide, which dissolves, and mercury, which remains undissolved. C. R. C. Tichborne found mercurous oxide rubbed with a 10 per cent. soln. of **sodium hydrocarbonate** mixed with phenolphthalein and made colourless by nitric acid does not give a red coloration. A. Fleischer found that mercurous oxide dissolves in a hot soln. of **ammonium thiocyanate**, some mercury separates, and a complex ammonium mercuric thiocyanate is precipitated when aq. ammonia is added to the soln. A. Duflos' preparation dissolved completely in **acetic acid**; H. Erdmann and P. Köthner obtained a white precipitate by treating the acetic acid soln. with **acetylene**. E. G. Burckhardt found the soln. in hot aq. **citric acid**, on cooling, gives a white mixture of mercurous and mercuric salts. J. Peschier stated mercurous oxide is soluble in a soln. of **gum arabic**. J. L. Gay Lussac and L. J. Thénard found that molten **potassium** or **sodium** decomposes mercurous oxide with *une lumière très-vive, et légère détonation*.

G. B. Bird treated a soln. of mercurous nitrate with an alcoholic soln. of potassium hydroxide, all cooled to -42° . A pale amber-coloured precipitate slowly formed which, with rise of temp., changed into the colours of mixtures of mercuric and mercurous oxides and mercury. It was assumed that the pale amber-coloured precipitate was **mercurous hydroxide**, HgOH . C. Reichard also thought that he obtained mercurous hydroxide by digesting mercurous arsenite with an aq. soln. of sodium carbonate. I. Bhaduri said mercurous hydroxide is soluble in hot water and sodium hydroxide; and almost insoluble in cold water.

§ 7. Mercuric Oxide

In the thirteenth century, the Latin Geber knew that when mercury is heated for a long time, it forms a red calx or oxide; and in his *Summa perfectionis magisterii* he stated that he prepared the calx as a brilliant sublimate by heating a mixture of mercury, nitre, and vitriol. Raymond Lully¹ also prepared the red oxide by calcining the salt obtained by dissolving mercury in nitric acid. The red oxide of mercury obtained by these two processes was known to later chemists—e.g. A. Libavius—as *mercurius calcinatus per se*, *mercurius præcipitatus per se*, *hydrargyri calcinatus ruber*, or *mercurius præcipitatus ruber*, etc. The action of heat on mercury and on this oxide was discussed by L. Lemery, R. Boyle, P. Bayen, etc.; and in 1774, there was a controversy between A. Baumé and L. C. Cadet de Gassicourt, as to whether in the absence of reducing agents the red oxide sublimes without decomposition, or is decomposed.

E. Bertrand² also found over 22 per cent. of mercuric oxide as an accessory mineral with the hydrargyrite of Los Bordes (Chili). Red rhombic needle-like crystals of mercuric oxide were found by A. J. Moses at Terlingua (Brewster County, Texas), and named *montroydite* after Montroyd Sharpe, a mine owner. The crystals occur mixed with mercury and mercuric sulphide. They were studied by W. F. Hillebrand and W. T. Schaller, and B. F. Hill.

The preparation of mercuric oxide.—Mercuric oxide occurs in two forms, yellow and red. Red mercury oxide was prepared by C. E. Weigel³ by keeping mercury for a month or longer at a boiling heat in a flask filled with air, and having a long loosely fitting tube adapted to its neck. The temp. must not be raised too high, or any oxide which may have been formed will be decomposed—according to W. H. Echols, the temp. of formation is 450°, and the temp. of decomposition 630°, at ordinary press. M. Rosenfeld found that the velocity of oxidation is greatly accelerated if the mercury contains a little potassium. G. B. Taylor and G. A. Hulett heated the mercury 4–7 days to 20° in oxygen under a press. of 2–3 atm. M. E. Chevreul found mercury is covered by a film in freshly prepared oxygen—ozone or chlorine may possibly have been present. H. B. Baker has shown that the vapour of mercury has very little attraction for oxygen. Mercuric oxide is also formed by heating mercury with an oxidizing agent—e.g. M. C. Schuyten

used potassium chlorate, and Geber, *vide supra*, nitre. F. L. Winkler reported the presence of some nitre in commercial red oxide of mercury.

F. C. Hoffmann, and J. B. van Mons heated mercurous or mercuric nitrate in a crucible or glass flask on a gradually rising temp. until the nitrous fumes ceased to be evolved. To economize nitric acid, the mercuric nitrate was triturated with an equal weight of mercury before the calcination. E. Kuhn prepared the mercurous nitrate for this purpose by dropping mercury into liquid nitrogen peroxide, and distilling off the excess of the latter. M. Payssé pointed out that if the nitric acid used for making the nitrate contained hydrochloric acid, the resulting oxide will be mixed with some oxychloride. If the nitrate is insufficiently heated—H. C. Vielhaber, C. Jehn, G. Patein—the oxide will contain undecomposed nitrate or some basic nitrate which, according to P. Carles, may be removed by boiling with dil. alkali-lye, or water. P. C. Ray and J. N. Sen calcined mercurous nitrite in a similar manner. G. Brusa and V. Borelli manufactured mercuric oxide by heating mercurous nitrate in a revolving drum connected with a similar revolving drum containing cold mercury. The oxygen and nitrogen peroxide from the hot drum form mercurous nitrate in the cold drum. The mercuric oxide is removed from the first drum, and when it has cooled mercury is introduced. The mercurous nitrate in the second drum is then heated and mercurous nitrate is formed in the first drum, and the operations are repeated again and again. J. Volhard, W. L. Hardin, G. Patein, etc., have given directions for purifying mercuric oxide. J. Myers removed any mercurous oxide in mercuric oxide by heating a mixture of the oxide with ammonium nitrate. The Elektrizitätswerk Lonza obtained mercuric oxide by the electrolysis of alkalies and oxysalts with a mercury anode, and removed the mercury by distillation below say 450° ; and the Consortium für Elektrochemie electrolytically oxidized mercury in a soln. of sodium carbonate.

L. V. Brugnatelli showed that mercuric oxide is formed by washing mercuric nitrate many times with boiling water; and N. A. E. Millon, by similarly washing basic mercuric nitrate, or mercuric acetate. The brown oxychloride, $4\text{HgCl}_2 \cdot \text{HgO}$, and the black oxychloride, $\text{HgCl}_2 \cdot 2\text{HgO}$, give red oxide when treated with a cold soln. of alkali hydroxide, or a hot soln. of alkali carbonate; many other oxychlorides under similar conditions furnish the yellow oxide. If a soln. of a mercuric salt be treated with an excess of potassium hydroxide, and washed, pale orange-yellow coloured oxide is formed, which, according to M. Siewert, after careful washing still retains one per cent. of mercuric chloride, potassium chloride, and potassium hydroxide. E. P. Schoch gradually added 100 c.c. of a hot soln. of mercuric chloride (1 : 2) to 500 c.c. of a hot soln. of potassium hydroxide (1 : 2), and boiled the mixture 5 hrs. in a flask fitted with a reflux condenser. The product was washed by decantation, and dried on a porous tile. If a cold sat. soln. of a mol of mercuric chloride be added to a cold 2–30 per cent. soln. of at least 10 mols of sodium hydroxide, a pale yellow powder is obtained which, after standing under the mother liquid for some weeks, acquires an orange colour. O. Brunck obtained the yellow oxide by treating a soln. of mercuric nitrate with an excess of sodium carbonate; E. Dufau treated a soln. of mercuric chloride with potassium carbonate; E. Bosetti used barium hydroxide. G. Pinchbeck also gave directions for preparing yellow mercuric oxide.

H. Gaudechon prepared a brown oxide by heating the red oxide to 400° . S. Kern obtained what he regarded as a modification of mercuric oxide by heating the grey precipitate obtained by the action of magnesium on a soln. of mercuric chloride. K. Schick cooled a sat. aq. soln. of mercuric oxide and obtained a white powder, which became yellow when warmed.

C. Paal⁴ prepared **colloidal mercuric oxide** by the action of sodium protalbinat or lysalbinat on a soln. of mercuric chloride; Kalle and Co. by the action of the sodium salt of proteic acids on a soln. of a mercuric salt; R. May and co-workers by the action of norgin on an alkaline soln. of mercuric chloride; and E. H. Bunce by the action of potassium hydroxide on an acetone soln. of mercuric chloride.

T. Svedberg obtained colloidal mercuric oxide by the action of an electric discharge on mercuric oxide under isobutyl alcohol. J. Hausmann studied the diffusion of potassium hydroxide in a soln. of mercuric chloride and gelatine.

The characteristics of red and yellow mercuric oxides.—Red mercuric oxide forms scaly shining crystals of a brick-red colour; it also forms a dull flocculent brownish-red crypto-crystalline powder. The colour of the red oxide by grinding becomes orange-yellow, and lighter coloured as the fineness increases. When obtained by precipitation, it forms a light orange-yellow or buff-yellow powder which, after heating, becomes red. J. T. Pelouze⁵ thought that yellow mercuric oxide is amorphous, and that red mercuric oxide is crystalline. L. Schaffner, and T. Carnelley and J. Walker believed that the yellow oxide is hydrated, but L. J. Proust, N. A. E. Millon, and W. Wallace showed that it is anhydrous like the red oxide; M. Siewert found a sample dried for 4 days in vacuo at 80° contained 0.5 per cent. of water; E. P. Schoch found a similar amount in a sample air-dried at 115°. According to E. P. Schoch, both the yellow and red oxides are crystalline. He said that the former forms microscopic square tablets, and that if the pale yellow crystals are left in contact with the liquid in which they have been formed, or in a soln. of sodium or potassium chloride, they increase in size, and the colour changes from pale yellow to orange, and in some weeks to a red tint. When the crystals of the yellow oxide are boiled with aq. soln. of salts, they are converted into the prismatic form of the red oxide; the same change takes place when the dry yellow oxide is heated at 250°–600° for 8–24 hrs. The colour of the oxide does not afford trustworthy evidence as to which form is present, since the tabular crystals of the yellow oxide sometimes exhibit a deeper colour than the prismatic crystals of the red variety. On the other hand, A. J. Allmand stated that both the yellow and red modifications occur in prisms and quadratic plates. J. L. Gay Lussac attributed the differences which have been observed in the physical and chemical properties of the two oxides, to a difference in the degree of fineness of the yellow and red oxides. The greater chemical activity of the yellow oxide is a result of the greater surface exposed to the reagent. W. Ostwald, and K. Schick also consider the two modifications to be identical except in the size of the grains.

The following differences in the properties of the red and yellow oxides have been reported. E. P. Schoch found the sp. gr. of the red oxide to be slightly lower than that of the yellow. The errors of experiment in determining the sp. gr. of fine-grained powders are always greater than with coarse-grained homogeneous material. J. T. Pelouze found that when equal quantities of the two oxides are ignited in the same muffle, the yellow oxide volatilizes completely in a time in which the decomposition of the red oxide has scarcely begun. J. L. Gay Lussac and N. A. E. Millon also found that the yellow oxide gives off rather more oxygen than the red in the same time when heated side by side, but the difference is slight. E. P. Schoch stated that the dissociation press. of the yellow oxide at 300°–320° is 760 mm., whereas that of the red does not exceed 400 mm. E. Cohen found a difference of 0.685 millivolt when the two forms of oxide are made into electrodes, $\text{Hg} | \text{HgO}, \text{KOH}$; but, according to G. Fuseya, this may be an effect of the greater solubility of the more finely divided oxide. According to J. T. Pelouze, dry chlorine acts very slowly on the red oxide at ordinary temp. and not much more quickly when the oxide is powdered, the reaction with the yellow oxide is so vigorous that the mass becomes red hot even when the yellow oxide has been pre-heated to 300–400°. J. L. Gay Lussac contradicted this in that he found dry chlorine gas produces less hypochlorous anhydride with the red than with the yellow oxide, and he attributed the difference to the smaller surface presented by the red oxide and the formation of a layer of mercuric chloride; the slowness of the reaction with the red oxide results in a slower rise of temp., and consequently this reaction is not so accelerated by temp. as with the yellow oxide. Under water, the two oxides are acted on by chlorine with nearly the same speed, because the mercuric chloride is dissolved as fast as it is formed. N. A. E. Millon found that the red oxide may be boiled with a soln. of oxalic acid without changing very much, while the yellow oxide, even in the cold, is quickly changed to white oxalate. J. Koster and S. J. Stork found that if the red oxide be ground in an agate mortar for 2 hrs. it is as readily acted upon by an aq. soln. of oxalic acid as the yellow oxide. N. A. E. Millon reported also that when boiled with an excess of a soln. of potassium dichromate, the yellow oxide forms the basic chromate, $3\text{HgO} \cdot \text{CrO}_3$, and the red oxide, $4\text{HgO} \cdot \text{CrO}_3$. E. Spelta found that when heated in a sealed tube at 150°, the yellow oxide reacts with sulphuryl chloride,

but not so with the red oxide. C. H. Hirzel stated that the yellow oxide, when dried at 40° – 50° , reacts with dry ammonia at 100° ; but when dried at 160° – 180° the oxide is not changed by dry ammonia at 150° . F. Köhler stated that the red oxide is not changed by cold or hot selenium dioxide, or selenic acid, while the yellow oxide forms a basic selenate; and C. F. Rammelsberg made a similar observation with respect to the action of iodic acid. O. Schmieder stated that the red oxide is sparingly soluble in an aq. soln. of ammonium sulphate, and that a white basic salt appears before the liquid is sat.; on the other hand, the yellow oxide readily dissolves in the liquid, and a basic salt separates after the liquid is sat. According to N. A. E. Millon, an alcoholic soln. of mercuric chloride converts the yellow oxide rapidly into oxychloride, $\text{HgCl}_2 \cdot 2\text{HgO}$, while the red oxide is scarcely affected. *Vide infra*, chemical reactions.

R. Varet found that the heat of neutralization with hydrocyanic acid is 31.58 Cals. for both the red and yellow oxides; the heat of formation of both oxides is the same, and no heat is evolved when the red oxide passes into the yellow one. The solubility of the yellow oxide in water is greater than that of the red oxide. This is in accord with the general observation that the solubility of a fine-grained powder is greater than that of a coarse-grained powder. G. A. Hulett found that the solubility of ordinary mercuric oxide at 25° is 0.050 grm. per litre, and when finely ground, the solubility rises to 0.150 grm. per litre. When still further comminuted, the solubility of the red oxide can be made to exceed that of the ordinary yellow oxide. R. T. Glazebrook and S. Skinner found that with Gouy's standard cell, the red oxide gives an e.m.f. of 1.384 volts, and the yellow oxide, 1.391 volts. E. Cohen obtained analogous results; but W. Ostwald showed that the differences depend on the different solubilities of the two oxides. Both oxides have approximately the same solubility in *N*-soln. of potassium bromide or iodide, sodium thiosulphate, etc. W. Bersch showed that mercuric oxide reacts with the alkali halides, e.g. $\text{HgO} + 2\text{KCl} + \text{H}_2\text{O} \rightleftharpoons 2\text{KOH} + \text{HgCl}_2$, until equilibrium is reached. The cell $\text{Hg} \mid \text{HgO}_{\text{yellow}} \mid \text{KOH}_{\text{soln.}} \mid \text{HgO}_{\text{red}} \mid \text{Hg}$, in consequence, gives an e.m.f. of 0.001 volt which is well within the range of experimental error.

The physical properties of mercuric oxide.—F. A. C. Gren⁶ said that mercuric oxide has a disagreeable metallic taste; and it is a violent acid poison. The **colour** has been previously discussed. F. A. C. Gren, E. J. Houston, and G. F. Hildebrandt showed that when the red oxide is heated, it darkens in colour and becomes violet-black, but the original red colour is restored on cooling (*vide* 2. 18, 13). E. P. Schoch also found that when the yellow oxide is heated under water, it becomes red, and the original yellow colour is restored on cooling. B. Schwalbe found that when the red oxide is cooled to -86° , it is nearly colourless. According to M. Saladin, obtuse rhombohedral **crystals** were formed in a bottle containing the pharmaceutical preparation *aqua phagadænica*—a mixture of lime-water and mercurous chloride. W. F. Hillebrand and W. T. Schaller found that the crystals of montroydite are holohedral and rhombic with the axial ratios $a:b:c = 0.6375:1:1.1977$. A. des Cloiseaux stated that the tabular crystals obtained by heating mercury for a long time in air are monoclinic prisms with axial ratios $a:b:c = 0.6728:1:0.3185$, and $\beta = 117^{\circ} 29'$; P. Groth recalculated the data and obtained $a:b:c = 0.5979:1:0.6367$, and $\beta = 90^{\circ} 56'$. O. G. Nordenskjöld obtained $a:b:c = 1.5330:1:1.4500$, and β approximately 90° , or, recalculated by P. Groth, $a:b:c = 1.1498:1:1.875$, and β approximately 90° . For E. P. Schoch's and A. J. Allmand's observations, *vide supra*.

A. le Royer and J. B. A. Dumas gave 11.29 for the **specific gravity** of mercuric oxide in vacuo; W. Herapath, 11.074–11.085 (17.5° – 18.3°); P. F. G. Boullay, 11.0; C. J. B. Karsten, 11.1909 (4°); L. Playfair and J. P. Joule, 11.136–11.344 at 3.9° ; and E. P. Schoch, at 27.5° , gave 11.03 for the yellow oxide, 11.08 for the red oxide, and for the red oxide finely ground, 11.21. W. F. Hillebrand and W. T. Schaller gave between 2 and 3 for the **hardness** of montroydite; and A. J. Moses gave less than 2. W. Spring studied the **effect of pressure** on mercuric oxide, and M. C. Lea reported that this oxide darkens slightly but very distinctly under press., and this change seems to be accompanied by a slight loss of weight, requiring, however, very careful weighing to detect it. The darkened part, as well

as the rest, dissolves without difficulty in acetic acid, and consisted, therefore, probably of traces of mercurous oxide and not of metallic mercury.

According to C. Zenghelis, mercuric oxide is volatile at ordinary temp., and a gold plate a short distance away is attacked, a silver plate more so. A. J. Allmand gave 6×10^{-22} atm. at 18° for the **dissociation pressure** of mercuric oxide; V. Rothmund gave $10^{-10.96}$ atm., or $10^{-8.08}$ mm. at room temp. G. B. Taylor and G. A. Hulett gave for the dissociation press., p , at T° K., $\log p = -5273.5T^{-1} + 1.75 \log T - 0.001033T + 5.9461$ —*vide* 1. 8, 2. J. Kendall and F. J. Fuchs found that the oxides of copper, manganese, iron, cerium, silicon, and chromium accelerated the thermal decomposition of mercuric oxide. J. Joubert found the oxide to be perceptibly decomposed at 100° . The **action of heat** is such that, according to W. H. Echols, decomposition begins at 630° , and combination at 450° . At a red heat, therefore, mercuric oxide volatilizes completely, for it is resolved into oxygen and mercury vapour, and if heated in a distilling apparatus, the mercury vapour takes up some oxygen on cooling, and this collects on the surface of the mercury in the receiver. E. P. Schoch found the dissociation press. of the yellow oxide is greater than that of the red oxide at about 300° —*vide supra*. The equilibrium conditions in the heterogeneous system $2\text{HgO} \rightleftharpoons 2\text{Hg} + \text{O}_2$ have been studied by J. Myers, H. Pélabon, H. Debray, H. W. B. Roozeboom, and G. B. Taylor and G. A. Hulett—*vide* 1. 8, 2. O. Brunck found that 2.5 to 4 per cent. of the oxygen is ozonized, but not if the oxide is heated in air; with a mixture of potassium chlorate and mercuric oxide, no ozone is formed. A. R. Leeds thought that the supposed ozone formed by heating mercuric oxide is really chlorine present as an impurity in the oxide. According to M. Goldstein, the **molecular heat** is 5.6. H. Kopp gave 0.0530 for the **specific heat** between 15° and 52° ; H. V. Regnault, 0.0518 between 5° and 98° ; and A. S. Russell, 0.0355 between -190° and -80° ; 0.0449 between -74° and 0° ; and 0.0503 between 3° and 43° . The **heat of formation** or decomposition, according to M. Berthelot, is 21.5 Cals.—the same for red or yellow oxide, as subsequently found by R. Varet—*vide supra*. J. Thomsen gave $(\text{Hg}, \text{O}) = 30.67$ Cals.; W. Nernst, 20.7 Cals.; R. Varet, 21.5 Cals.; and G. B. Taylor and G. A. Hulett, 21.4 Cals.

E. L. Nichols and B. W. Snow measured the **reflecting power** for light of different wave-length at 25° , 313° , and 523° . Mercuric oxide gradually blackens when exposed to sunlight, being superficially decomposed into mercury and oxygen, according to N. J. B. G. Guibourt, or into mercury and mercurous oxide, according to M. Donovan. No evolution of gas was observed by G. Lemoine during the decomposition of mercuric oxide in sunlight. M. Berthelot found that red mercuric oxide is more rapidly decomposed by sunlight than the yellow oxide; this is partly due to the colour and to the texture of the powder; the action is much increased if moisture be present. G. A. Dima studied the **photoelectric effect** of mercury oxide; and N. R. Campbell, the **radioactivity**.

K. Schick found the sp. **electrical conductivity** of aq. soln. to be 2.1×10^{-6} at 25° . A. J. Allmand has measured the **difference of potential** with red and yellow mercuric oxide, and N - and $\frac{1}{10}N$ -soln. of potassium or sodium hydroxide. M. Chow measured the e.m.f. of hydrogen and mercuric oxide cells, and of mercuric oxide and amalgam cells. A. Iljef measured the **thermoelectric force** of two pencils of compressed mercuric oxide. J. Habermann, and P. Bunge, showed that a mercury cathode with a 1 cm. layer of mercuric oxide does not give off hydrogen in the electrolysis of organic liquids. P. T. Muller and H. Allemandet, and A. Heil considered the use of mercuric oxide as a **depolarizer** in galvanic elements.

The chemical properties of mercuric oxide.—Mercuric oxide is readily reduced by hydrogen. S. Hauser⁷ found the temp. of the reduction of the yellow oxide to be 64° – 76° ; and of the red oxide, 164° – 195° . According to A. Colson, the yellow oxide reduced about five times as rapidly as the red oxide; the rapidity of attack is not proportional to the press. but more nearly to the cube root of the press. W. Müller-Erbach observed no reduction by hydrogen at 200° , a slight action at 220° , and more at 230° ; and with the yellow oxide the action begins at 127° . I. W. Fay

and A. F. Seeker detected a reduction with the yellow oxide at 50°, and with the red oxide at 115°; F. Glaser's numbers are respectively 75° and 91° for the yellow and red precipitated oxide, and 140° for the red oxide prepared by heating mercury in oxygen. F. G. Donnan and A. J. Allmand compute the thermal value $\text{H}_2 + \text{HgO} = \text{Hg} + \text{H}_2\text{O} + 46.75$ Cals. from measurements of the e.m.f. A. von Antropoff found that the red oxide suspended in water is not changed by the passage of **ozonized oxygen** for three days. M. Traube found mercuric oxide is oxidized by **hydrogen peroxide**; and M. Martinon, that it is reduced by hydrogen peroxide in alkaline soln.

According to A. L. Lavoisier and C. M. Cornette⁸ precipitated yellow mercuric oxide is soluble in **water**, but not the red oxide. L. Thompson and N. J. B. G. Guibourt also noted the solubility of mercuric oxide in water. E. F. Anthon found the oxide to be sparingly soluble in cold, and more soluble in hot water. The statement, however, was contested by the early workers, and some believed that the alleged solubility was a mal-observation due to the use of an oxide contaminated with the nitrate; but R. F. Marchand, F. H. Boudet, and A. Gossmann showed that the oxide free from nitrate is dissolved by water. A. Bineau found that a litre of water dissolves 0.033 grm. of yellow or red mercuric oxide; and W. Wallace, that a litre of water dissolves 0.005 grm. of yellow oxide after standing for a long time in contact with one another, and 0.008 grm. after boiling and cooling. G. A. Hulett found a litre of water at 25° dissolves 0.05 grm. of coarse-grained red oxide, and 0.15 grm. of the fine-grained red oxide. K. Schick gave for the solubility of the yellow oxide in a litre of soln., 0.0518 grm. at 25°, and 0.410 grm. at 100°; and the red oxide, 0.0513 grm. at 25°, and 0.379 grm. at 100°—longer contact would probably have given better agreement between the results with the red and yellow oxides. He estimated 2 per cent. **ionization** occurs in aq. soln. A. J. Allmand gave for the **solubility product**, 4×10^{-26} at 18°; H. Grossmann gave the same value; and S. Labendzinsky, 1.5×10^{-26} .

According to H. Moissan,⁹ **fluorine** attacks mercuric oxide with the development of heat. M. Braamcamp and S. Oliva found that at a red heat, **chlorine** decomposes mercuric oxide into oxygen and mercuric chloride, but at lower temp., chlorine monoxide and mercuric chloride or oxychloride are formed; and with mercuric oxide suspended in boiling water, chlorine forms mercuric chloride and chlorate. A. Michael and A. Murphy found that a 10 per cent. soln. of chlorine scarcely attacks mercuric oxide under conditions where the gas readily attacks the oxide. According to E. Lippmann, a soln. of **iodine** in water, alcohol, benzene, acetone, or carbon tetrachloride—but not in alcoholic phenol—when boiled with mercuric oxide in a reflux condenser forms mercuric iodide, and an oxyiodide—possibly the iodate: $6\text{HgO} + 6\text{I}_2 = 5\text{HgI}_2 + \text{Hg}(\text{IO}_3)_2$. K. Brückner noted the formation of mercuric iodide and iodate in aq. soln., but in alcoholic soln. some aldehyde was formed. R. L. Taylor noted that freshly precipitated mercuric oxide gives mercuric hypiodite when treated with iodine dissolved or suspended in water. A. Jäger found the solubility of mercuric oxide in aq. **hydrofluoric acid** of normality *N*, to be:

<i>N</i>	0.12	0.24	0.57	1.11	2.17
Mol per litre	0.01258	0.0247	0.0629	0.1168	0.2586

If alkali fluorides be also present the solubility is reduced; H. Pick gave 1.8×10^{-25} for the solubility product. O. D. Sweet found that **hydrochloric acid** mixed with ammonium chloride is a good solvent for mercuric oxide. S. M. Tanatar and L. Pissarjewsky found the heat of soln. in 0.1*N*-alcoholic soln. hydrochloric acid to be 18.9 Cals., and M. Berthelot gave 9.45 Cals. for the heat of neutralization of $\frac{1}{2}\text{HgO}$ with hydrochloric acid (one eq. per litre). According to E. P. Schoch, the water solubility of mercuric oxide is raised in the presence of **alkali chlorides**; C. Jehn, and H. Grossmann found the oxide to be readily soluble in a soln. of **potassium iodide**, forming, according to E. Rupp and W. F. Schirmer, potassium hydroxide and potassium mercuric iodide, K_2HgI_4 . G. André, found mercuric

oxide to be soluble in conc. soln. of the **alkaline earth chlorides** and of **magnesium chloride**. W. Bersch found that the **alkali halides** are decomposed by mercuric oxide, forming the mercuric halide and the alkali hydroxide until equilibrium is attained, but if an insoluble mercuric halide is formed, and an excess of mercuric oxide be present, all the halogen is abstracted from the soln. The state of equilibrium is dependent on the heat of reaction; if heat is absorbed, the quantity of free alkali increases with rise of temp. and *vice versa*. The time required to reach the final state of equilibrium is dependent on the halogen—it is smallest with the iodides, and decreases as the temp. is raised. The amount of decomposition depends mainly on the halogen, the alkali metal has very little influence on the result. O. Kühling, M. Dranty, and E. Dufau studied the action of soln. of **sodium chloride**. According to W. R. Hodgkinson and F. K. Lowndes, when mercuric oxide is added to molten **potassium chlorate**, there is an increase in the speed of evolution of oxygen, and chlorine is formed. O. Brunck also studied this reaction, *vide supra*.

When mercuric oxide is heated with **sulphur** in a retort, L. J. Proust¹⁰ observed a violent explosion; and J. B. Senderens found that by rubbing together sulphur, mercuric oxide, and a little water, and heating the mixture to 100°, mercuric sulphide and sulphate were formed. F. C. Phillips found that mercuric oxide suspended in water is slowly turned grey and then blackened by **methyl hydrosulphide**. R. W. Bunsen used mercuric oxide for oxidizing metal sulphides into oxides, F. W. Schmidt said that basic sulphates may be formed. According to D. L. Hamrick, **sulphur dioxide** is oxidized by heated mercuric oxide forming mercury, sulphur trioxide, and mercurous and mercuric sulphates. A. Vogel found that mercuric oxide is reduced by **sulphurous acid** to sulphuric acid and mercury; but if the proportion of sulphurous acid be small, there is a rise of temp. and some mercurous sulphate, Hg_2SO_4 , is formed, and in part dissolved; that in soln. is very slowly reduced by the sulphurous acid to mercury. The precipitation is complete if sufficient acid be present. G. Oddo and U. Giachery represented the quantitative reaction with **sulphur monochloride**: $2\text{HgO} + 2\text{S}_2\text{Cl}_2 = 2\text{HgCl}_2 + \text{SO}_2 + 3\text{S}$. E. Spelta noted that **sulphuryl chloride**, SO_2Cl_2 , does not react with cold or hot mercuric oxide prepared in the dry way; but with the yellow oxide, mercuric sulphate and chloride are formed. H. B. North found sulphuryl chloride reacts slowly at ordinary temp. and press. with the yellow oxide and a mixture of mercurous and mercuric chlorides was formed in a few days. The yellow oxide acts more vigorously than the red oxide when heated with sulphuryl chloride in a sealed tube—some sulphur trioxide is formed. The yellow oxide reacts vigorously with **thionyl chloride**, SOCl_2 , and a white mixture of mercurous and mercuric chlorides is formed; with a large proportion of thionyl chloride: $\text{HgO} + 5\text{SOCl}_2 = \text{HgCl}_2 + 3\text{SO}_2\text{Cl}_2 + \text{S}_2\text{Cl}_2$; and with a small proportion: $\text{HgO} + \text{SOCl}_2 = \text{HgCl}_2 + \text{SO}_2$. K. Barth noted that a complex is formed when mercuric oxide is treated with **sodium hydrosulphate**: $\text{HgO} + 2\text{NaHSO}_4 = \text{Hg}(\text{NaSO}_4)_2 + \text{H}_2\text{O}$. W. Spring found mercuric oxide reacts with sodium hydrosulphate under the influence of great press. J. Landauer and F. J. Faktor found mercuric oxide is blackened by **sodium thiosulphate**, and mercuric sulphide is formed. A. Seyewetz and P. Trawitz found that the oxide dissolves in a hot soln. of **ammonium persulphate**, giving off oxygen and forming a sulphate.

According to J. Kjeldahl,¹¹ and C. Arnold and K. Wedemeyer, mercuric oxide at 400° acts as an oxidizing agent for **nitrogen**, and can be utilized in organic analytical work. G. Gore and E. C. Franklin and C. A. Kraus found both yellow and red mercuric oxides are insoluble in liquid **ammonia**. A. L. Lavoisier referred to the solubility of mercuric oxide in aq. ammonia; and he added that on evaporation the soln. furnishes a white salt in which the mercuric oxide *fait alors l'office d'acide*. L. Cramer obtained what he regarded as *mercuric dotrita-ammino-oxide*, $3\text{HgO} \cdot 2\text{NH}_3$, by mixing an emulsion of gum arabic and mercuric oxide with ammonia. It is stated to blacken on exposure to light. S. Hauser studied the reduction of mercuric oxide by ammonia gas. A. Guyard found the oxide is soluble in ammoniacal soln.

of **ammonium salts**. F. Ephraim found **sodamide** is reduced and sodium amalgam is formed. According to P. Sabatier and J. B. Senderens, **nitric oxide** is not changed by mercuric oxide at 300°, but at 400°, nitrous fumes are formed and the oxide dissociates. According to W. Lossen, and A. Thum, **hydroxylamine** rapidly reduces mercuric oxide to the metal; the reaction has been studied by W. Zorn, E. Divers, W. F. C. Dresler and R. Stein, and M. Adams. The latter found the oxide is dissolved at 0° by an alcoholic soln. of hydroxylamine hydrobromide. Mercuric oxide is vigorously reduced by **hydrazine** hydrate, and the reaction has been studied by T. Curtius and R. Jay, F. Schrader, L. de Bruyn, A. W. Browne and F. F. Shetterly, etc. C. F. Hale and V. E. Nunez represented the reaction: $\text{N}_2\text{H}_4 \cdot \text{H}_2\text{O} + 2\text{HgO} = \text{N}_2 + 2\text{Hg} + 3\text{H}_2\text{O}$. O. D. Sweet found **nitric acid** to be a good solvent for mercuric oxide. E. Divers found the **hyponitrites** are oxidized by mercuric oxide to nitrites.

A mixture of mercuric oxide and **phosphorus** detonates when struck with a hammer; and when boiled with water and phosphorus. B. Pelletier¹² noted that mercury phosphide and phosphoric acid are formed; at ordinary temp. M. Braamcamp and S. Oliva, and A. Granger found that mercury is produced, but they say that no phosphoric or phosphorous acid appears to dissolve in the water—possibly a phosphate is formed; they also stated that **phosphorous acid** reduces mercuric oxide to mercury, and phosphoric acid is formed. B. E. Howard also found **hypophosphorous acid** reduces mercuric oxide explosively to the metal. K. Haack found mercuric oxide to be insoluble in **phosphoric acid**, **arsenic acid**, and in soln. of the primary and secondary **alkali phosphates** and **alkali arsenates**. C. Reichard studied the action of red and yellow mercuric oxides on soln. of arsenious oxide in sodium hydroxide, and when the soln. is warmed, the mercury is reduced. A. Vogel found powdered **antimony** reduces mercuric oxide when the mixture is heated.

According to A. Gautier,¹³ **carbon monoxide** does not act on moist mercuric oxide; but I. W. Fay and A. F. Seeker found that the yellow oxide is reduced in 6 hrs. at 0°, and the red oxide likewise at 95°. L. Moser and O. Schmid said that the yellow oxide is quantitatively reduced at 100°, but not the red oxide. S. Hauser gave 95° for the temp. of the reaction with red oxide, and 50° with the yellow oxide. F. von Kùgelgen reduced mercuric oxide by heating it with **calcium carbide**. C. R. C. Tichborne found that a red coloration appears when mercuric oxide is triturated with a 10 per cent. soln. of **sodium hydrocarbonate** mixed with phenolphthaleïn, and just decolorized with nitric acid. L. N. Vauquelin found that the action of mercuric oxide on **cyanogen** resembles that of the alkali hydroxides—the undissolved oxide turns brown, and mercuric cyanide and ammonium carbonate are formed. M. Berthelot gave for the heat of the reaction at 15° between mercuric oxide and **hydrocyanic acid** (1 eq. per litre), 31 Cals. for the solid salt, and 34 Cals. for the salt in soln. G. McP. Smith found red mercuric oxide reacts in the cold with a soln. of potassium ferricyanide, forming ferric hydroxide, potassium hydroxide, and mercuric cyanide; with an excess of the ferricyanide, mercuric oxide dissolves, ferric hydroxide is deposited, and the soln. deposits crystals of mercuric cyanide. F. Selmi found that when **ferric potassium ferrocyanide**—soluble prussian blue—is boiled with water and mercuric oxide, mercuric cyanide is formed; **silver ferrocyanide** was found by W. Weith to have very little action; **potassium cobalticyanide** to have none at all; F. Sönderop found that a boiling soln. of potassium cobalticyanide form potassium hydroxide and cobaltous mercuricyanide, $\text{CO}_2\text{Hg}_3\text{Cy}_{12}$; E. Lehmann, that **potassium manganicyanide**, K_3MnCy_6 , forms mercuric cyanide and manganese sesquioxide; C. Rölcke, that **potassium chromicyanide**, K_3CrCy_6 , forms chromium hydroxide, mercuric cyanide, and chromous mercuricyanide, $\text{Cr}_2\text{Hg}_3\text{Cy}_{12}$; the Badische Anilin- und Sodafabrik patented the formation of ammonia by the action of mercuric oxide on **titanium cyanonitride**. A. Fleischer found mercuric oxide is copiously dissolved by cold or hot soln. of **ammonium thiocyanate**.

Mercuric oxide acts as an oxidizing agent on many organic compounds and is thereby reduced to mercurous oxide or the metal—e.g. A. Vogel found soln. of **sugar**

or **lactose** reduced mercuric to mercurous oxide, and in the presence of potassium hydroxide, A. C. Becquerel found the metal is produced. According to P. Sabatier and A. Mailhe, **alcohol** at 150° – 250° forms carbon dioxide and acetaldehyde—not acetic acid; and, according to F. Bullnheimer, **glycerol** reduces the oxide to the metal. A. Connell found that mercuric oxide dissolves in a boiling mixture of acetic and formic acids, and P. A. von Bonsdorff found that this oxide is not decomposed with a soln. of potassium chloride and **sodium formate**, but when heated with potassium chloride and free **formic acid**, carbon dioxide is evolved, and some potassium formate, mercuric chloride, and mercury are produced. K. Brand studied the solvent action of **trichloroacetic acid**; W. Traube and B. Löwe, that of **ethylene-diamine**; K. A. Hofmann, of **acetone**, **propyl alcohol**, **benzene**, **chloroform**, **petroleum**, etc.; H. Wilfarth showed that the presence of mercuric oxide accelerates the oxidation of organic substances by sulphuric acid; and A. Halenke used it for oxidizing organic matters. H. Erdmann and H. Köthner found that mercuric oxide favoured the continuous formation of acetaldehyde by passing acetylene into a boiling mixture of sulphuric acid and water. Mercuric oxide is soluble in picric acid (R. Varet); alkali phenoldisulphonate (A. and L. Lumière and M. Chevrotier); formamide (B. Fischer and B. Grützner); benzamide (V. Dessaignes); soln. of gum arabic (J. Peschier); etc. Mercuric oxide forms complexes with many organic compounds. According to S. M. Auld and A. Hantzsch, freshly precipitated mercuric oxide does not dissolve in acetone, but it readily dissolves if a trace of alkali hydroxide is present; it behaves similarly with **acetaldehyde**; and it does not dissolve in **acetophenone** unless the mixture is warmed to 100° .

E. Lay¹⁴ found mercuric oxide decomposed heated silicon hydrogen-nitrogen compounds—*e.g.* $\text{Si}_2\text{N}_3\text{H}$; O. Ruff and K. Albert reduced **silicochloroform**, SiHCl_3 ; and G. Rauter reduced **silicon tetrachloride**, SiCl_4 , between 250° and 260° . C. Chabré and F. Levallois found **ultramarine** is desulphurized by treatment with silver chloride. J. L. Gay Lussac and L. J. Thénard¹⁵ found that mercuric oxide is reduced by molten **potassium** or **sodium** in a similar manner to mercurous oxide. N. N. Beketoff obtained a mixture of Na_2Hg and Na_2HgO_2 by heating eq. quantities of sodium and mercuric oxide. C. Winkler reduced the oxide by heating it with **magnesium**; A. Vogel, by heating it with **zinc** or **tin** filings; and A. Stavenhagen and E. Schuchard, by warming it with **aluminium**.

E. P. Schoch¹⁶ stated that mercuric oxide is not much more soluble in an aq. soln. of **sodium hydroxide** than it is in water, but K. Schick stated that its solubility in $\frac{1}{50}$ *N*-KOH is 25 per cent. greater than in water. G. Fuseya found the solubility of mercuric oxide at 25° , when *K* denotes the equilibrium constant, to be:

NaOH	.	.	0	0.0096	0.0955	0.502	1.0758	2.09 mols per litre.
HgO	.	.	23.4	24.6	24.9	26.6	28.3	30.9 millimols per litre.
K	.	.	—	—	0.0047	0.0049	0.0050	0.0051

The sudden change in the solubility of the oxide in passing from neutral to alkaline soln. is thought to be due to the greater dispersion of the mercuric oxide in alkaline soln. Assuming that the steady increase in the solubility of mercuric oxide as the conc. of the sodium hydroxide increases, is due to the hydrated mercuric oxide acting as a weak acid, **mercuric acid**, H_2HgO_2 , and since the increase in solubility is proportional to the first power of the conc. of the OH' -ion, G. Fuseya represents the reaction $\text{Na}' + \text{OH}' + \text{HgO}_{\text{solid}} = \text{Na}' + \text{HHgO}_2'$, and calculates the equilibrium constant *K*, from $K = [\text{HHgO}_2'] / [\text{OH}']$. He estimated the ionization constant of the first hydrogen of mercuric acid to be 1.7×10^{-15} . J. Hausmann studied the diffusion of mercuric chloride in gelatine containing **potassium hydroxide** in soln. S. Meunier showed that a little mercuric oxide readily dissolves in molten potassium hydroxide over 400° without the evolution of gas, forming a colourless liquid. The cold cake when slowly cooled is brownish-violet, and when extracted with water furnishes some amorphous mercuric oxide and rhombic octahedra of **potassium mercuriate**, $\text{K}_2\text{Hg}_2\text{O}_3$ —sp. gr. 10.31. When the crystals are heated, the mercuric

oxide volatilizes from the crystals, and leaves behind potash. They are gradually decomposed by water, and more slowly still by alcohol. S. Meunier obtained similar crystals of what he regarded as **sodium mercuriate**, $\text{Na}_2\text{Hg}_2\text{O}_3$, in an analogous manner. K. Schick obtained what was assumed to be **barium mercuriate**, $\text{BaHg}_2\text{O}_3 \cdot \text{H}_2\text{O}$, by mixing a 0.26*N*-soln. of barium hydroxide with levigated yellow mercuric oxide. C. L. Berthollet boiled mercuric oxide with lime-water, and on evaporation obtained yellow crystals thought to be **calcium mercuriate**.

B. Finzi said that mercuric oxide dissolves in soln. of **silver sulphate, nitrate, or acetate**. V. Kohlschütter and A. d'Almendra found that if mercuric oxide be immersed in a soln. of silver nitrate containing some free acetic acid, a deposit of metallic silver is formed on the oxide—*vide* zinc oxide. A. Mailhe precipitated basic salts by adding mercuric oxide to soln. of **cupric chloride, bromide, or nitrate**, while **cupric sulphate** is but slowly and incompletely attacked. Basic salts were also obtained by A. Mailhe, and G. André from soln. of **zinc chloride, bromide, or nitrate**; the former found no precipitation occurs with **cadmium sulphate**, but basic salts were obtained with **cadmium chloride, bromide, or nitrate**. L. Barthe found mercuric oxide to be sparingly soluble in a cold soln. of **mercuric cyanide**, but copiously at 75° with the evolution of hydrocyanic acid. A. Vogel noted that an aq. soln. of **stannous chloride** gives a precipitate of the metal and a basic salt—stannic chloride is formed. A. Mailhe obtained a precipitation of basic chloride from soln. of **lead chloride**, but no visible change with **lead nitrate** soln. Basic bismuth chloride is precipitated when mercuric oxide is dissolved in a cold soln. of **bismuth trichloride**; a basic bismuth nitrate also precipitates from soln. in **bismuth nitrate**. E. F. Smith and P. Heyl found that chromium, iron, and aluminium are completely precipitated as hydroxides or basic salts from soln. of their salts by the addition of mercuric oxide, while zinc, cobalt, nickel, uranium, beryllium, cerium, and lanthanum are partially precipitated from cold soln., and more completely from hot soln. B. Finzi also examined the action of soln. of salts of chromium, aluminium, manganese, iron, nickel, and cobalt on mercuric oxide. C. Zimmermann found that mercuric oxide does not precipitate uranyl hydroxide from soln. of **uranyl nitrate**, but it does so quantitatively from **uranyl chloride** soln. or mixtures of the nitrate with alkali chloride; and G. Alibegoff used the reaction for the separation of uranium from the alkalies and alkaline earths. A. Mailhe found that mercuric oxide is soluble in soln. of uranium nitrate and **aluminium nitrate** and a basic mercuric nitrate is formed; and also that freshly precipitated mercuric oxide added to soln. of **manganous chloride** causes the separation of manganese hydroxide which rapidly forms a higher oxide and an oxychloride; no visible change occurs with soln. of **manganous sulphate**; and a manganomercuric nitrate is obtained in soln. of the nitrate. J. Volhard, and C. Meineke precipitated manganese dioxide, MnO_2 , by treating a soln. of **manganese sulphate or nitrate** with mercuric oxide and bromine water. According to A. Duflos, mercuric oxide is reduced to mercurous oxide by **ferrous hydroxide** or **ferrous salts**; A. Mailhe obtained a precipitation of a basic ferric chloride from soln. of **ferrous chloride**; a basic sulphate from soln. of **ferrous sulphate**; a basic mercuric salt from soln. of **ferric chloride, ferric sulphate, or ferric nitrate**. He also obtained a precipitation of basic salts from soln. of **nickel chloride or nitrate**; and from soln. of **cobalt chloride or nitrate**. C. Zimmermann utilized the reaction for separating cobalt and nickel from iron and aluminium chlorides or sulphates.

Mercuric hydroxide.—The aq. soln. of mercuric oxide, according to N. J. B. G. Guibourt,¹⁷ and M. Donovan has a metallic taste, and when exposed to the air, becomes covered with a film of mercury; it is coloured brown by hydrogen sulphide; and gives a white turbidity when slightly diluted with ammonia; and it also colours the juice of violets green. J. Fonberg found that the soln. does not act on turmeric; and F. H. Boudet, that it colours litmus blue; A. Bineau also stated that it acts on litmus after admixture with a salt soln. N. Pappada found colloidal mercuric oxide to be soluble in a soln. of mercuric oxide. T. Carnelley

and J. Walker claimed to have made mercuric hydroxide, $\text{Hg}(\text{OH})_2$, by adding sodium hydroxide to a soln. of mercuric chloride, and drying the precipitate in air; only about $\frac{1}{2}$ per cent. of water is lost at 100° , and all—about 8.5 per cent.—is lost at 175° ; at higher temp. oxygen begins to be evolved. The ionic solubility found by W. Biltz and F. Zimmermann is about 10^{-9} ; and H. Ley and H. Kissel said that the basicity of mercuric hydroxide is very small, and approaches that of aniline. M. Kolthoff saw that the ionization of mercuric hydroxide involves the consecutive reactions $\text{Hg}(\text{OH})_2 \rightleftharpoons \text{HgOH}^+ + \text{OH}^- \rightleftharpoons \text{Hg}^{++} + 2\text{OH}^-$. When mercuric hydroxide is boiled with an ammonium salt soln., H. Grossmann found that complex salts are formed. N. G. Chatterji and N. R. Dhar said that mercuric hydroxide is peptized by soln. of sodium hydroxide in the presence of glycerol or sugar because the electrical conductivity of the alkali soln. is not appreciably changed by the mercuric hydroxide.

Mercuric dioxide or peroxide.—According to A. von Antropoff,¹⁸ mercurous oxide reacts with hydrogen peroxide with explosive violence even in the presence of free acid; after repeated additions of peroxide, the reaction ceases, and the black oxide assumes a dark red colour, due to the formation of mercuric peroxydate. Mercuric dioxide seems to be formed in the catalytic decomposition of hydrogen peroxide; and by the interaction of an alcoholic soln. of mercuric chloride with hydrogen peroxide in the presence of the theoretical amount of potassium hydroxide in alcoholic soln. G. Pellini prepared this compound in a similar manner. Some specimens of red oxide immediately decompose the hydrogen peroxide with evolution of oxygen, but the addition of a minute quantity of nitric acid will prevent this and induce the formation of the peroxydate. The compound cannot be obtained by the action of hydrogen peroxide on mercuric acetate, or by the action of ozone on mercury or mercuric oxide. Analyses of the red compound show that it has the composition HgO_2 , and it can be regarded as the mercuric salt of hydrogen peroxide, that is, *mercuric-peroxydate*, $\text{Hg}(\text{O.O})$. It decomposes rapidly when in contact with water at the ordinary temp. with evolution of oxygen. It is slowly hydrolyzed by water at 0° ; the washings contain free hydrogen peroxide, and mercuric oxide is formed ultimately. The dark red compound is not formed when the red oxide is left in contact with hydrogen peroxide of 15 per cent. or less conc., although even in these cases evolution of oxygen occurs after some little time. The peroxydate is formed more readily at the ordinary temp. than at 0° , but this is followed by vigorous decomposition in the course of twenty to fifty minutes, whereas at 0° decomposition occurs after three to seven days. The decomposition is accelerated by traces of alkali, but retarded by acids. Yellow mercuric oxide cannot be used in place of the red oxide, but, if the red oxide is powdered until it has a yellow colour, it reacts readily with hydrogen peroxide; the product formed has a paler colour, and decomposes much more readily than the product from the ordinary red oxide. When dry, the compound is comparatively stable, even at ordinary temp. It can undergo rapid decomposition, leaving a grey residue; this usually occurs at the beginning of drying; or it can decompose slowly, giving up oxygen and leaving a residue of red mercuric oxide. When heated or struck, it explodes, and the product obtained from the finely powdered oxide explodes when rubbed, even in the moist state. Daylight has no apparent effect on the decomposition of the dry powder. Acids decompose mercuric dioxide, forming mercuric salts and hydrogen peroxide; with hydrochloric acid chlorine is evolved; with potassium iodide, iodine is formed; and a soln. of potassium permanganate is decolorized. The feeble basic character of mercury corresponds with the relative instability of the compound when compared with the corresponding dioxides of magnesium, zinc, and cadmium.

§ 8. Mercury Ammonium Compounds

Neither mercuric-amide, $\text{Hg}(\text{NH}_2)_2$, nor mercuric-imide, HgNH , has been prepared, although a derivative of phenylamine, $\text{C}_6\text{H}_5\text{NH}_2$, namely, mercuric phenylamide, $\text{Hg}(\text{NHC}_6\text{H}_5)_2$, has been obtained. Reactions which might have been expected *a priori* to give these compounds—e.g. treatment of potassamide in liquid ammonia with a mercuric salt—give the end-product, mercuric nitride, Hg_3N_2 ; thus, with mercuric iodide: $3\text{HgI}_2 + 6\text{KNH}_2 \rightarrow \text{Hg}_3\text{N}_2 + 6\text{KI} + 4\text{NH}_3$.

Mercurous ammonia compounds.—Numerous ammonia derivatives of mercuric salts are known, but not of mercurous salts. Hydrazine, which resembles ammonia in some respects, is reported to form with mercurous nitrate, a white crystalline addition compound, mercurous hydrazine nitrate, $\text{N}_2\text{H}_4 \cdot 2\text{HgNO}_3$; but the corresponding ammonia compound has not yet been obtained. It seems as if mercurous compounds break down into mercury and mercuric salts as soon as the attempt is made to prepare ammonia derivatives. This is supposed to be explained by assuming that the mercurous chloride is slightly dissociated: $2\text{HgCl} \rightleftharpoons \text{Hg} + \text{HgCl}_2$, and the equilibrium is slightly disturbed by the addition of ammonia, for the ammonia reacts with the mercuric chloride, forming an insoluble amide; this

reduces the conc. of the mercuric salt, and accordingly more is formed to restore equilibrium, and as this action continues the dissociation proceeds to an end. This corresponds with the fact that nearly all the mercurous ammonia compounds which have been reported are black—presumably owing to the presence of free mercury in a finely divided state. J. G. F. Druce¹ said that hydrochloric acid is first produced in the reaction and then neutralized. According to the routine process employed in qualitative analysis, when separating a mixture of mercurous and silver chlorides, the mercurous chloride is turned black on the addition of aq. ammonia; the black substance was formerly considered to be *dimercuroammonium chloride*; later, the black precipitate was thought to be a *dimercuric amidochloride* formed by the reaction:

and later still, a mixture of finely divided mercury, and mercuric chloroamide. The evidence is as follows: If a thin layer of the black precipitate be spread on glass and dried, it will lose weight in the course of a few days, and assume a greyish-white colour. The loss in weight is explained on the assumption that the black substance is a mixture of free mercury and **mercuric chloroamide**, $\text{Cl}-\text{Hg}-\text{NH}_2$, and that the mercury volatilizes leaving behind the $\text{Cl}-\text{Hg}-\text{NH}_2$. The reaction is therefore symbolized: $2\text{HgCl} + 2\text{NH}_3 \rightarrow \text{Hg} + \text{Cl.Hg.NH}_2$. One proof that the black precipitate contains metallic mercury turns on the fact that if mercurous and silver chlorides be jointly precipitated and allowed to stand for some time in contact with ammonia, some metallic silver is formed by the action of the free mercury: $\text{AgCl} + \text{Hg} = \text{Ag} + \text{HgCl}$. Hence, in a qualitative analysis, "if silver be not found in the filtrate from the black precipitate, the latter should be examined for that metal." Similarly, mercurous ammonia chloride, HgCl.NH_3 , said to be formed by the action of dry ammonia on solid mercurous chloride is really a mixture of mercury and a white precipitate, contaminated with ammonium chloride. J. G. F. Druce found the black solid does not appreciably amalgamate copper; this would favour the assumption that free mercury is not present.

The constitution of the mercury nitrogen compounds.—Many hypotheses have been suggested for the constitution of the mercury nitrogen compounds derived from ammonia, and therefore the constitutional formulæ which have been assigned to them, as well as their names, are considered to be more or less arbitrary. These compounds are insoluble in ordinary solvents, and they are decomposed by heat. Hence, their mol. wt. are a subject of conjecture rather than of demonstrated fact, and hypotheses about their constitution are proportionally vague.

C. F. Rammelsberg's diammonium theory.—C. F. Rammelsberg (1839) assumes the ammonia mercury compounds can be referred to ammonia by replacing its hydrogen atoms one by one. L. Pesci and P. C. Ray consider that all the mercury ammonia compounds can be referred to *one primary type*, *dimercuriammonium*, $(\text{Hg}_2\text{N})'$, in which the four hydrogen atoms of ammonium are replaced by two atoms of bivalent mercury, and that the primary compounds have a great tendency to form double salts by union with ammonium or mercuric compounds.

K. A. Hofmann and E. C. Marburg's substituted ammonium theory.—K. A. Hofmann and E. C. Marburg (1899) and others assume that there are several primary types which can act as radicles, e.g.:

R. J. Kane's substituted ammonia theory.—R. J. Kane (1839) assumed that these compounds are either addition products or amine- or amido-derivatives of ammonia. E. C. Franklin (1907) rejects the ammonium theories, and extends Kane's idea so as to include an interesting analogy between reactions involving ammonia and those involving water. There are ammonio-basic salts and mixed ammonio- and hydro-basic salts as well as addition compounds of ammonia.

As might be anticipated, some writers propose a compromise between these diverse views, and state that "substitution products both of ammonia and of ammonium compounds exist as well as compounds formed by the addition combination of ammonia with mercuric salts." The following, based on the work of E. C. Franklin, is convenient for purposes of classification :

Mercuric amines.—In these compounds, the ammonia appears to be related to the metallic salt in a manner analogous with the so-called water of crystallization of ordinary hydrated salts. The compounds are formed by direct addition of the mercuric halide with ammonia. For instance, the so-called *fusible white precipitate* is an additive compound of ammonia and mercuric chloride, $\text{HgCl}_2 \cdot 2\text{NH}_3$. It is formed by pouring a soln. of mercuric chloride drop by drop into a boiling soln. of ammonia and ammonium chloride as long as any of the precipitate dissolves. Rhombic crystals separate from the cooling soln. The same compound is formed when mercuric chloride is dissolved in liquid ammonia. This fusible white precipitate has been variously regarded as a **mercuric diamminochloride**, $(\text{NH}_3)_2\text{HgCl}_2$, or $\text{HgCl}_2 \cdot 2\text{NH}_3$, in which ammonia plays the part of ammonia of crystallization ; or as *mercuridiammonium chloride*, $\text{NH}_3\text{Cl}-\text{Hg}-\text{NH}_3\text{Cl}$; or, according to C. F. Rammelsberg, as $\text{Hg}_2\text{NCl} \cdot 3\text{NH}_4\text{Cl}$. When diamminomercuric chloride is boiled with a 20 per cent. soln. of potassium hydroxide, it is decomposed giving off, according to K. A. Hofmann and E. C. Marburg (1899), the eq. of all its nitrogen as ammonia, and according to L. Pesci (1889), three-fourths of its nitrogen as ammonia. There must be a mal-observation here. The former statement agrees with the symmetry of the nitrogen atom in the molecule and the latter with the dissymmetry of three-fourths of the nitrogen atoms in the mol. The sparing solubility of the compound is not in favour of Rammelsberg's formula. The existence of two **mercuric aminiodides**, $3\text{HgI}_2 \cdot 4\text{NH}_3$, and $\text{HgI}_2 \cdot 2\text{NH}_3$, and the ready decomposition of $\text{HgI}_2 \cdot 2\text{NH}_3$ into mercuric iodide and ammonia favour the "ammonia of crystallization" theory of the constitution of fusible white precipitate. The ethylamine derivative of fusible white precipitate, **mercuric ethyldiamminochloride**, $\text{HgCl}_2 \cdot 2\text{C}_2\text{H}_5\text{NH}_2$, is prepared by using ethylamine in place of ammonia. The constitutional formula for this compound is adapted to the dimercuriammonium theory of Rammelsberg— $\text{Hg}_2\text{NCl} \cdot 3\text{NH}_4\text{Cl}$ —and the similarity in the mode of formation of the ethylamine and the ammonia derivatives makes it *a priori* probable that the two compounds are constituted alike. Several other derivatives of the substituted ammonias—phenylamine, benzylamine, pyridine, urea, etc.—have been similarly prepared.

When fusible white precipitate is heated, it fuses (hence the name), forming a yellow fluid which gives off some nitrogen and ammonia. As a rule, the halide derivatives decrease in stability with increasing at. wt. of the contained halogen ; this is shown in the present case by the fact that the vap. press. of the ammonia in the chloride is virtually zero, while with the diamminomercuric iodide, $\text{HgI}_2(\text{NH}_3)_2$, the vap. press. of the ammonia is quite appreciable, being equal to 8 mm. of mercury at 0° ; to 37 mm. at 25° ; and to 601 mm. at 75° . It might be added that vap. press. measurements show no signs of the compound, $\text{HgI}_2 \cdot \text{NH}_3$; the decomposition press. of $\text{HgI}_2(\text{NH}_3)_2$ is considerable, and the compound loses ammonia on exposure to the air. Several related compounds with mercuric bromide, cyanide, sulphate, nitrate, acetate, dichromate, thiocyanate, etc., have been prepared. Some of these contain water as well as ammonia—*e.g.* $\text{HgI}_2\text{NH}_3 \cdot \text{H}_2\text{O}$.

Ammoniobasic compounds.—These compounds are formed when a soln. of mercuric chloride is treated with a slight excess of ammonia, or when mercuric chloride is poured into a large excess of ammonia. If an excess of ammonia be present in the soln. when a fusible white precipitate is being prepared ammoniolysis occurs, and a substitution product, *infusible white precipitate*, or **mercuric amidochloride**, $\text{Hg}(\text{NH}_2)\text{Cl}$, is formed : $\text{HgCl}_2 \cdot 2\text{NH}_3 \rightleftharpoons \text{NH}_4\text{Cl} + \text{Hg}(\text{NH}_2)\text{Cl}$. Conversely, infusible white precipitate is converted back to fusible white precipitate by the action of a soln. of ammonium chloride in liquid ammonia. If water is present, hydrolysis as well as ammoniolysis

will simultaneously occur. Thus, fusible white precipitate, $\text{HgCl}_2 \cdot 2\text{NH}_3$, is converted by ammoniolysis into infusible white precipitate, $\text{Hg}(\text{NH}_2)\text{Cl}$, as just indicated, and by hydrolysis into the so-called *Millon's base*, $\text{HgOH} \cdot \text{NH} \cdot \text{HgCl}$, by a reaction symbolized: $2\text{NH}_2\text{HgCl} + \text{H}_2\text{O} \rightleftharpoons \text{NH}_4\text{Cl} + \text{HgOH} \cdot \text{NH} \cdot \text{HgCl}$. The compound NH_2HgCl is regarded as an ammoniobasic salt in the same sense that $\text{HO} \cdot \text{Hg} \cdot \text{Cl}$ would be regarded as a hydrobasic salt. Most of the ammoniobasic salts of the heavy metals are hydrolyzed by water, and accordingly can be formed only in soln. of liquid ammonia or of some inert solvent. The mercuric ammoniobases and salts are exceptional in their stability towards water. Hundreds have been reported as mercuriammonium compounds.

Infusible white precipitate, $\text{NH}_2\text{Hg} \cdot \text{Cl}$, is related to ammonia much as a basic salt, say $\text{HO} \cdot \text{Hg} \cdot \text{Cl}$, is related to water. C. F. Rammelsberg represented this compound as a double salt of dimercuriammonium chloride, $\text{Hg}_2\text{NCl} \cdot \text{NH}_4\text{Cl}$. As evidence against this hypothesis, there is (i) the formation of a **mercuric ethylamidochloride**, $\text{NH}(\text{C}_2\text{H}_5)\text{HgCl}$, by the action of ethylamine, $\text{NH}_2(\text{C}_2\text{H}_5)$, on an excess of mercuric chloride; and the previous remarks about the ethylamine derivative of fusible white precipitate apply to the ethylamine analogue of infusible white precipitate; (ii) the sparing solubility of infusible white precipitate, an unexpected property, since the ammonium salts of the complex acid, $\text{H}(\text{HgNCl}_2)$, *nach allen analogien*, should be more soluble than is actually the case. K. A. Hofmann and E. C. Marburg consider that R. J. Kane's formula is in harmony with the fact that when boiled with an excess of 20 per cent. potash-lye, all the nitrogen is given off as ammonia. When heated, infusible white precipitate decomposes into ammonia and nitrogen without melting (hence the name), and a residue of mercurous chloride remains: $6\text{NH}_2\text{HgCl} \rightarrow \text{N}_2 + 4\text{NH}_3 + 6\text{HgCl}$. When digested with water, infusible white precipitate breaks down into ammonium chloride and an **oxydimercuric-amidochloride**, $\text{OHg}_2\text{NH}_2\text{Cl}$. In symbols:

Infusible white precipitate is soluble in conc. ammonia, and when the soln. is allowed to evaporate in vacuo, over sulphuric acid, crystals separate. These when dried at 100° have a composition corresponding with what R. J. Kane regarded as NH_2HgCl .

According to N. A. E. Millon, precipitates containing the eq. of between 75 and 85 per cent. of mercury can be obtained by pouring aq. ammonia into soln. of mercuric chloride. The composition of the precipitate depends upon the temp. and conc. of the soln., on the rate of admixture, and on the amount of washing to which the precipitate is subjected. Hence, it is very probable that many mixtures have been reported as chemical compounds—mere analysis is not sufficient to establish chemical individuality.

Guided by the phase rule, D. Strömholm studied the mutual solubility of ammonium and mercuric chlorides in water, and found that four double or complex salts—(i) $\text{HgCl}_2 \cdot 2\text{NH}_4\text{Cl} \cdot \text{H}_2\text{O}$; (ii) $\text{HgCl}_2 \cdot \text{NH}_4\text{Cl} \cdot \text{H}_2\text{O}$; (iii) $2\text{HgCl}_2 \cdot 2\text{NH}_4\text{Cl} \cdot \text{H}_2\text{O}$; (iv) $9\text{HgCl}_2 \cdot 2\text{NH}_4\text{Cl}$ —were stable as solid phases when the conc. of the mercuric chloride is progressively increased, and that of the ammonium chloride progressively diminished. Similarly, R. Widman (1910) has studied the conditions of equilibrium in systems containing different proportions of ammonium bromide, mercuric bromide, and ammonia, and found that the following five compounds are capable of existence: $\text{HgBr}_2 \cdot 2\text{NH}_3$; NH_2HgBr ; $(\text{HgBr})_2\text{NH}$; NHg_2Br ; and $\text{Hg}_9\text{N}_4\text{Br}_6$.

Millon's base.—This compound is formed in yellow rhombic crystals by the action of aq. ammonia on mercuric oxide: $2\text{HgO} + \text{NH}_4\text{OH} = (\text{HgOH})_2\text{NH}_2\text{OH}$. Following K. A. Hofmann and E. C. Marburg, E. C. Franklin regarded Millon's base as a **dimercurihydroxyammonium hydroxide**. According to C. F. Rammelsberg's scheme, Millon's base is considered to be $\text{Hg}_2\text{NOH} \cdot 2\text{H}_2\text{O}$, where the two mols. of water play the rôle of water of crystallization. The chloride of the base

does not lose its water at 125°; the water is lost only when the mol. breaks down completely at 180°. This agrees better with the formula $\text{HgO}(\text{NH}_2)\text{HgCl}$, or $(\text{HgOH})_2\text{NH}_2\text{Cl}$ for the chloride of Millon's base, and with $\text{HgO}(\text{NHg}_2)\text{HgOH}$ or $(\text{HgOH})_2\text{NH}_2\text{OH}$ for Millon's base itself. The ethylamine derivative of Millon's base, $\text{HgOH.N}(\text{C}_2\text{H}_5)\text{HgCl}$, like the ethylamine derivative of fusible and infusible white precipitates, is cited as an argument in favour of the constitutional formulæ HgOH.NH.HgCl . E. Weitz (1915) represents the relation between these three compounds as follows:

which implies hydrolytic actions with $\text{NH}_3.\text{Hg}(\text{OH})\text{Cl}$ as an intermediate product. The hydrolysis of the infusible precipitate which furnishes mercuric oxide and ammonium chloride, proceeds $\text{NH}_2\text{HgCl} + \text{H}_2\text{O} \rightleftharpoons \text{HgO} + \text{NH}_4\text{Cl}$, and the mercuric oxide unites with a second mol. of NH_2HgCl to form the chloride of Millon's base. According to this view, Millon's base is constituted $\text{HgO}(\text{NH}_2)\text{HgOH}$.

When Millon's base is boiled with potash-lye, it loses a mol. of water to form the so-called *first anhydride of Millon's base*, a feebly explosive compound, represented as 2HgO.NH_3 , or $\text{O} \begin{array}{c} \text{Hg} \\ \diagup \quad \diagdown \\ \text{H} \end{array} \text{N} \begin{array}{c} \text{H}_2 \\ \diagdown \quad \diagup \\ \text{OH} \end{array}$, or, according to E. C. Franklin, HgOH.NH.HgOH .

E. C. Franklin likens this reaction to the hydration of a metallic oxide to a hydroxide in virtue of the marked tendency of mercury to replace hydrogen in many of the derivatives of ammonia. Water reacts with calcium oxide to form calcium hydroxide, but ammonia, in the absence of water, reacts with mercuric oxide to form not HO.HgNH_2 , but rather a derivative of this, *viz.* $(\text{HOHg})_2\text{NH}$, and this reacts with water, forming Millon's base, $(\text{HOHg})_2\text{NH}_2\text{OH}$. With Franklin's formula, the basic properties of the first anhydride are referred to the characteristic, slightly basic, properties of mercuric hydroxide, and with K. A. Hofmann and E. C. Marburg's formula, to the persistence of the properties of the contained ammonia. The former hypothesis agrees better with the characteristic tendency of halogens to unite with mercuric compounds. A *second anhydride of Millon's base* is represented by the empirical formula Hg_2NOH , and Franklin's graphic formulæ for these compounds are:

This view is in accord with the action of dil. acids on hydroxyl bases, converting them into basic salts, *e.g.* the chloride of Millon's base HgOH—NH—HgCl ; while more conc. acids change them into neutral salts, *e.g.* HgCl—NH—HgCl , is made by the action of aq. ammonia on an excess of a boiling soln. of mercuric chloride.

Salts of Millon's base.—In addition to the chloride, various other salts of Millon's base have been prepared—bromide, iodide, fluoride, bromate, sulphate, nitrate, carbonate, cyanide, thiocyanate, etc. The action of ammonia on mercuric sulphate, of a soln. of ammonium sulphate on mercuric oxide or basic mercuric sulphate, or of dil. sulphuric acid on Millon's base, furnishes a white powder which has been obtained in octahedral crystals. This compound is the sulphate of Millon's base, and has been called *ammonia turpeth*; it has the empirical formula $\text{Hg}_4\text{N}_2\text{H}_4\text{O}_8$, or graphically, $\text{HgOH.NH.HgSO}_4.\text{HgNH.HgOH}$. It does not lose water when heated to 115°. When mercuric nitrate is dissolved in a boiling soln. of ammonium nitrate, the cooling soln. deposits needle-like crystals with the empirical formula $\text{Hg}_2\text{N}_3\text{H}_{12}\text{O}_{12}.3\text{NO}_3$, which is usually dissected into $\text{Hg}(\text{NO}_3)_2.2\text{NH}_3.2\text{H}_2\text{O.NH}_2\text{HgNO}_3$, and called *Kane's salt* because it was first prepared by R. J. Kane. Another nitrate called *Mitscherlich's salt* is supposed to have the composition $\text{NH}_2\text{HgNO}_3.\text{HOHgNH.HgNO}_3$, and is prepared by treating a dil. barely acid soln. of mercuric nitrate with dil. aq. ammonia—not in excess. The nitrate of Millon's base, called

Soubeiran's salt, $\text{HgOH}-\text{NH}-\text{HgNO}_3$, is prepared by the action of a slight excess of ammonia on a dil. soln. of mercuric nitrate; by the action of boiling water on Mitscherlich's salt, or of water on Kane's salt. Several other nitrates have been reported; they can all be regarded as products of hydrolysis and ammoniolysis.

In view of the fact that the systematic name for these compounds is dependent upon the particular hypothesis employed as to their constitution, there is an advantage in employing such unsystematic arbitrary names as Millon's base, fusible and infusible white precipitate, etc., for the names do not then change with a change in fashion or mode of viewing their constitution.

By the action of an excess of conc. ammonia on mercuric iodide, or the action of Nessler's reagent on ammonia, a brownish precipitate **mercurihydroxyimidoiodide**, $\text{HgOH}-\text{NH}-\text{I}$, is formed (Nessler's reaction). When Millon's base is heated in a stream of ammonia, a dark brown explosive compound, Hg_2NOH , or graphically $\text{HOHg}-\text{N}=\text{Hg}$, is formed by the loss of two mols. of water, and the anhydrous oxide, $(\text{Hg}_2\text{N})_2\text{O}$, has been made. A compound with the empirical formula NHg_2I is precipitated when a soln. of potassamide is mixed with an excess of, say, mercuric iodide dissolved in liquid ammonia. Its constitution is probably **mercuric iodonitride**, $\text{HgN}-\text{Hg}-\text{I}$, and not dimercuric ammonium iodide. It appears to be a relation of $\text{NH}_2\text{Hg.I}$ obtained by replacing two atoms of hydrogen by bivalent mercury. A similar **mercuric bromonitride**, NHg_2Br , has been prepared.

Hydroxylamine, NH_2OH , and hydrazine, N_2H_4 , form addition products with mercuric chloride. With water, the hydrazine compound splits off hydrazine chloride, $\text{N}_2\text{H}_4\cdot\text{HCl}$, and forms $\text{HgCl}\cdot\text{NH}\cdot\text{NH}\cdot\text{HgCl}$, or $(\text{HgCl})_2\text{N}_2\text{H}_2$, in the same way that fusible white precipitate splits off ammonium chloride and forms infusible white precipitate. A series of mercuriphosphorus bases has been made by K. A. Aschan (1886), and of mercuriarsenic bases by A. Partheil and E. Amort (1898) analogous with the mercuric nitrogen compounds. Thus, $\text{Hg}=\text{H}-\text{HgCl}$ is analogous with $\text{Hg}=\text{P}-\text{HgCl}$; and $\text{NH}(\text{HgCl})_2$ with $\text{AsH}(\text{HgCl})_2$.

A series of products has been obtained in which the hydrogen of the hypothetical ammonium oxide, $(\text{NH}_4)_2\text{O}$, is replaced by bivalent mercury, thus furnishing the mono- and tetra-hydrates of dimercuriammonium oxide, $(\text{NHg}_2)_2\text{O}\cdot\text{H}_2\text{O}$, $(\text{NHg}_2)_2\text{O}\cdot 4\text{H}_2\text{O}$; the anhydrous oxide and the di-, tri-, and penta-hydrates are probably doubtful. There is also a dimercuriammonium monamminoxide, $(\text{NHg}_2)_2\text{O}\cdot\text{NH}_3$.

W. Weyl² claimed to have made anhydrous **dimercuriammonium oxide**, $(\text{NHg}_2)_2\text{O}$, by the action of liquid ammonia on mercuric oxide contained in one leg of a sealed W-tube, silver chloride sat. with ammonia being warmed in the other leg; and also by warming the trihydrate, and keeping the trihydrate over sulphuric acid. H. Gaudechon claimed to have made it by the action of dry ammonia on the monohydrate between 100° and 110° . W. Weyl thinks that the mercuric nitride prepared by C. H. Hirzel by the action of ammonia on precipitated mercuric oxide is this compound. K. A. Hofmann and E. C. Marburg could not get a product with less combined water than NHg_2OH by the action of ammonia on mercuric oxide at 125° for 3 hrs. E. C. Franklin represents this compound by the formula: $\text{Hg}:\text{N}\cdot\text{Hg}\cdot\text{O}$. $\text{Hg}\cdot\text{N}:\text{Hg}$, but he doubts if it has yet been prepared. According to H. Gaudechon, the heat of formation from the elements is -75.3 to 76.6 Cals., and the heat of neutralization of the solid with hydrochloric acid is $(\text{NHg}_2)_2\text{O}+2\text{HCl}=(\text{NHg}_2\text{Cl})_2$. $\text{H}_2\text{O}+52.9$ Cals. The compound is not soluble in liquid ammonia. It explodes violently by heat, percussion, or friction. It explodes when warmed in hydrogen; it hydrates rapidly in humid air free from carbon dioxide; it absorbs carbon dioxide very slowly, forming a crust of carbonate; it is completely decomposed by water at 100° into mercuric oxide and ammonia; likewise also the dissolution of potassium chloride or hydroxide; hydrogen chloride rapidly acts on the dry compound that is formed, and mercuric and ammonium chlorides are formed. According to W. Weyl, hydrochloric or nitric acid dissolves it without residue, but, according to H. Gaudechon, it is not completely soluble in hydrochloric acid since some mercurous chloride

is formed. W. Weyl found that it is dissolved by a soln. of potassium cyanide at 130° .

W. Weyl prepared **monohydrated dimercuriammonium oxide**, $(\text{NHg}_2)_2\text{O} \cdot \text{H}_2\text{O}$, or NHg_2OH , by dehydrating the trihydrate in a stream of ammonia; K. A. Hofmann and E. C. Marburg, by heating Millon's base (*vide infra*) to 125° in a stream of ammonia, or by heating dry yellow mercuric oxide to 120° in ammonia; H. Gaudechon, by heating the tetrahydrate under diminished pressure in the presence of barium oxide, or by heating the tetrahydrate to 40° or 50° in a stream of dry ammonia. C. F. Rammelsberg kept dimercuric hemiammoniodioxide, $2\text{HgO} \cdot \text{NH}_3$, or $\text{NHg}_3\text{OH} \cdot \text{H}_2\text{O}$, over quicklime. E. C. Franklin represented its constitution by the formula $\text{Hg} : \text{N} \cdot \text{Hg} \cdot \text{OH}$; W. Weyl, by $(\text{NHg}_2)_2\text{O} \cdot 0.3\text{H}_2\text{O}$; H. Fürth, by $\text{O} : \text{Hg}_2 : \text{NH} \cdot \text{H}_2\text{O}$; and K. A. Hofmann and E. C. Marburg, by $\text{HO} \cdot \text{N} : \text{Hg}_2 \cdot \text{H}_2\text{O}$. The last-named gave 8.52 for the sp. gr. H. Gaudechon gave for the heat of formation $(\text{NHg}_2)_2\text{O} + \text{H}_2\text{O}_{\text{solid}} = (\text{NHg}_2)_2\text{O} \cdot \text{H}_2\text{O} + 1.6$ Cals. K. A. Hofmann and E. C. Marburg found that this compound can be preserved in closed vessels; but all observers agree that the compound is explosive; and W. Weyl said that the brown flocculent powder is less stable than the trihydrate; H. Gaudechon, that it is stable in air up to 20° , and at 50° no ammonia is lost. C. F. Rammelsberg found that ammonia is not lost either over sulphuric acid or over phosphorus pentoxide, although about 4.01 per cent. of water is given off, and that it probably forms at a higher temp., $(\text{NHg}_2)_2\text{O}$, and mercuric oxide and mercuric nitride, when heated still more. W. Weyl stated that under water it forms the trihydrate; and H. Gaudechon, that in water vapour free from carbon dioxide at 10° or 20° and about 10 mm. press., it gradually absorbs water, forming the tetrahydrate. K. A. Hofmann and E. C. Marburg stated that the compound gradually absorbs moisture from the air, and becomes non-explosive. W. Weyl found that it is easily soluble in hydrochloric acid; K. A. Hofmann and E. C. Marburg, that while it is soluble in dil. hydrochloric acid, a conc. soln. of hydrogen chloride in ether does not attack it, for the group NHg_2OH does not seem to be able to unite with acid radicles. H. Gaudechon found liquid ammonia converts it slowly into garnet-red **dimercuriammonium aminoxide**, $(\text{NHg}_2)_2\text{O} \cdot \text{NH}_3$, when the excess of ammonia is removed at -21° . It is stable at -21° under a press. of 750 mm. of mercury.

The so-called *dihydrated dimercuriammonium oxide*, $(\text{NHg}_2)_2\text{O} \cdot 2\text{H}_2\text{O}$, was reported by N. A. E. Millon as a product of the dehydration of the tetrahydrate; and he added that the brown mass could be heated without explosion; that it is insoluble in water or alcohol; that it is scarcely attacked by boiling conc. potassium hydroxide, but is decomposed by the molten hydroxide into nitrogen, mercury, and mercuric oxide; that with a hot soln. of ammonium nitrate chloride, sulphate, acetate, or oxalate, ammonia is evolved; and that water decomposes it into a green compound. E. C. Franklin and H. Gaudechon believe that N. A. E. Millon was mistaken in assuming that his product is the dihydrate in question, and H. Gaudechon also said that it is very unlikely that *trihydrated dimercuriammonium oxide*, $(\text{NHg}_2)_2\text{O} \cdot 3\text{H}_2\text{O}$, exists, although C. F. Rammelsberg gave it the formula $\text{NHg} \cdot \text{NOH} \cdot \text{HgOH}$, which E. C. Franklin believes is improbable; K. A. Hofmann and E. C. Marburg give $\text{O} : \text{Hg}_2 : \text{N} : \text{H}_2(\text{OH})$; and H. Fürth, $\text{HO} \cdot \text{Hg} \cdot \text{O} \cdot \text{Hg} \cdot \text{NH}_3$. N. A. E. Millon and C. H. Hirzel obtained what they regarded as the trihydrate by drying the higher hydrate over sulphuric acid; K. A. Hofmann and E. C. Marburg, by drying Millon's base, protected from light, in an atm. of ammonia, over potassium hydroxide; C. F. Rammelsberg, by drying the hydrate, $(\text{NHg}_2)_2\text{O} \cdot 4\frac{1}{2}\text{H}_2\text{O}$, over potassium hydroxide, calcium oxide, sulphuric acid, or phosphorus pentoxide, and also by the action of dry ammonia on yellow mercuric oxide; and W. Weyl, by shaking mercuric oxide for some hours with alcoholic ammonia, and drying it in air at ordinary temp., or by saturating yellow mercuric oxide with ammonia at ordinary temp., grinding the product, and again saturating with ammonia. If the press. of the ammonia be $2\frac{1}{2}$ atm. the action proceeds much more quickly. The general behaviour of the brown product is very much like that of the higher hydrate.

H. Gerresheim prepared **tetrahydrated dimercuriammonium oxide**, $(\text{NHg}_2)_2\text{O} \cdot 4\text{H}_2\text{O}$, by allowing freshly precipitated mercuric oxide, free from alkali, to stand for several days at 40° – 60° in aq. ammonia, free from carbon dioxide. The aq. ammonia is decanted off, and the product is washed first with alcohol, then with

ether, and rapidly dried. H. Gaudechon used a somewhat similar process, and he also exposed the monohydrate to water vapour as previously indicated; he obtained greenish-yellow crystals, and gave for the heat of formation $4\text{HgO} + 2\text{NH}_{3\text{aq}} + \text{H}_2\text{O} = (\text{NHg}_2)_2\text{O} \cdot 4\text{H}_2\text{O} + 14.4$ Cals. According to H. Gerresheim, the yellow powder becomes superficially grey when exposed to light for some time. It crackles continuously when rubbed in a mortar; when exposed to dry air, or when heated to $50^\circ\text{--}60^\circ$, it becomes brown and loses water; when heated to a higher temp. it decomposes—explosively if the rise of temp. be rapid. H. Gaudechon found that this compound becomes brown in vacuo over phosphorus pentoxide, and forms the monohydrate—some nitrogen is also given off; he added that the tetrahydrate is stable only in the presence of water vapour and ammonia. H. Gerresheim found the tetrahydrate to be slightly soluble in water, a litre of water at 17° dissolving 0.077 grm. of the tetrahydrate, and at 80° , 0.588 grm. Minute crystals are obtained on cooling the sat. soln.

The tetrahydrate was found by H. Gaudechon to be stable in water free from carbon dioxide, but at 100° it is gradually decomposed with the formation of mercuric oxide—and this in platinum vessels so that it is not an effect of alkali in the glass; if carbon dioxide be present, mercuric carbonate is formed, and a skin of the carbonate protects the tetrahydrate from the action of the water. The reaction is thought to be reversible: $(\text{NHg}_2)_2\text{O} \cdot 4\text{H}_2\text{O} \rightleftharpoons 4\text{HgO} + 2\text{NH}_3 + \text{H}_2\text{O}$, since on cooling, the ammonia left in soln. slowly recombines with the mercuric oxide. Liquid ammonia reacts with the tetrahydrate, forming in the course of a few days a garnet-red compound—possibly $(\text{NHg})_2\text{O} \cdot \text{NH}_3$, *vide supra*. According to H. Gaudechon and H. Gerresheim, a soln. of potassium hydroxide does not act on the tetrahydrate, and when it decomposes in a boiling soln. of this alkali, the decomposition is thermal not chemical. The latter obtained a brown explosive product by evaporating the tetrahydrate with a soln. of potassium hydroxide, and he added that nitric acid converts it into a white insoluble salt; hydrochloric acid gives a white chloride soluble in excess of the acid; dil. sulphuric acid forms an insoluble sulphate; conc. sulphuric acid colours it brown; and acetic acid yields a soluble acetate. The sulphate and nitrate are not precipitated from the soln. of the salt, and it is thought that in these salts the arrangement of the atoms is different from that in the original, because of the difference in their behaviour towards hydrochloroplatinic acid. With soln. of various salts, the tetrahydrate seems to unite with the acid radicle without the base passing into soln., and if an excess of the salt is present, the base dissolves if a soluble double salt is formed—*e.g.* most ammonium salts—or it dissolves with decomposition—*e.g.* potassium iodide, cyanide, or ferrocyanide, or sodium sulphide—or it remains undissolved—*e.g.* most salts. H. Gerresheim also studied the action of ethyl bromide and iodide, which form the iodide of the base; chloroform, which forms a gas, the chloride, and the formate of the base; and carbon disulphide, which forms the thiocarbonate of the base.

C. F. Rammelsberg obtained a hygroscopic pale yellow powder by the action of aq. ammonia on mercuric oxide; its composition was between $2\text{HgO} \cdot \text{NH}_3 \cdot \text{H}_2\text{O}$ and $2\text{HgO} \cdot \text{NH}_3 \cdot \frac{1}{2}\text{H}_2\text{O}$, or *hemiannahydrated dimercuriammonium oxide*, $(\text{NHg}_2)_2\text{O} \cdot 4\frac{1}{2}\text{H}_2\text{O}$. The general properties resemble those of the other hydrates. L. J. Proust, and P. Plantamour prepared what has been regarded as *pentahydrated dimercuriammonium oxide*, $(\text{NHg}_2)_2\text{O} \cdot 5\text{H}_2\text{O}$, by digesting mercuric oxide with a warm aq. soln. of ammonia free from carbonate. R. J. Kane, C. H. Hirzel, and N. A. E. Millon studied the reaction. The last-named also obtained the pentahydrate by warming dimercuriammonium salts with alkali hydroxide; and H. Fürth, by precipitating mercuric acetamide with aq. ammonia. The latter represented the constitution of the salt by $\text{HOHg} \cdot \text{O} \cdot \text{Hg} \cdot \text{NH}_3\text{OH}$; K. A. Hofmann and E. C. Marburg, as $(\text{HgOH})_2\text{NH}_2\text{OH}$, not as $\text{NHg}_2\text{OH} \cdot 2\text{H}_2\text{O}$; E. C. Franklin, as a mixed hydro-ammonio-base, $2\text{HgO} \cdot \text{NH}_3 \cdot \text{H}_2\text{O}$, or $\text{Hg}(\text{OH})_2 \cdot \text{Hg}(\text{NH}_2)\text{OH} \cdot 3\text{Hg}(\text{OH})_2 \cdot \text{Hg}(\text{NH}_2)_2$; and later, as $\text{HO} \cdot \text{Hg} \cdot \text{NH} \cdot \text{Hg} \cdot \text{OH} \cdot \text{H}_2\text{O}$. H. Gaudechon said that if this compound exists at all, it is unstable at 0° , since the tetrahydrate does not take up an appreciable amount of water, if kept 8 days at 0° in an atm. sat. with water vapour. According to J. L. Proust, P. Plantamour, R. J. Kane, and N. A. E. Millon, the pale yellow powder decomposes on exposure to light; it decrepitates without explosion when rubbed in a mortar, but at a dull red heat, it explodes not so vigorously as fulminating gold. When confined over

sulphuric acid C. H. Hirzel found that it lost nearly the eq. of $2\text{H}_2\text{O}$, and N. A. E. Millon, that it lost at 130° nearly the eq. of $3\text{H}_2\text{O}$, and that the product obtained with yellow mercuric oxide loses its water more readily than that prepared from the red oxide. K. A. Hofmann and E. C. Marburg found that it loses the eq. of H_2O over potassium hydroxide, and thereby becomes less stable and loses ammonia; absolute alcohol was also found to abstract water, forming a brown substance, which becomes yellow and then gradually decomposes into mercuric oxide, water, and ammonia. E. C. Franklin represents the dehydration changes: $(\text{HgOH})_2 : \text{NH}_3 \cdot \text{H}_2\text{O} \rightarrow \text{HgOH} \cdot \text{NH}_3 \cdot \text{HgOH} \rightarrow \text{HgOH} \cdot \text{N} : \text{Hg}$. R. J. Kane found that when heated it decomposes into ammonia, nitrogen, mercuric oxide, and water vapour. N. A. E. Millon and G. C. Wittstein said that the pentahydrate is insoluble in water or alcohol; and that aq. ammonia dissolves only traces; the former found that a cold soln. of potassium hydroxide does not attack the pentahydrate, but with a boiling soln. incomplete decomposition occurs, and ammonia is evolved; it attracts moisture from the air; it forms salt-like products with acids; and behaves like the dihydrate with soln. of ammonium salts. P. Plantamour obtained a brownish powder by the action of dry ammonia at 150° .

The so-called *Millon's base* is an ammonio-hydroxy-base, **dimercurihydroxy-ammonium hydroxide**, $(\text{HgOH})_2 \cdot \text{NH}_2\text{OH}$, or $\text{HgOH} \cdot \text{NH}_3 \cdot \text{HgOH} \cdot \text{H}_2\text{O}$. According to E. C. Franklin, the simplest ammonio-hydroxy-base is $\text{NH}_2 \cdot \text{Hg} \cdot \text{OH}$ intermediate between $\text{HO} \cdot \text{Hg} \cdot \text{OH}$, and $\text{NH}_2 \cdot \text{Hg} \cdot \text{NH}_2$, but it has not yet been isolated; Millon's base may be regarded as being formed from this hypothetical base by the loss of ammonia: $2(\text{NH}_2 \cdot \text{Hg} \cdot \text{OH}) = \text{HgOH} \cdot \text{NH}_3 \cdot \text{HgOH} + \text{NH}_3$. The product of the action of aq. ammonia on mercuric oxide contains one or one-and-a-half mol. of water. H. Gerresheim obtained yellow crystals of the base by keeping mercuric oxide and aq. ammonia in a sealed vessel for six months. K. A. Hofmann and E. C. Marburg digested for 12 hours, in darkness mercuric oxide, precipitated at 70° , with an aq. soln. of ammonia, free from carbon dioxide; the product was dried by suction and washing with absolute alcohol and ether. H. Gaudechon always found Millon's base to be contaminated with a little carbonate. H. Endemann and G. A. Prochaza recommended washing out the hydrochloric acid, sulphuric acid, carbon dioxide, and silica by a soln. of normal sodium carbonate. When Millon's base is dried in vacuo over sulphuric acid there remains a dark brown non-explosive product assumed to have the composition $\text{NHg}_3\text{O}_2\text{H}$, but which is probably a mixture. The general properties of Millon's base were shown by E. C. Franklin to be such as might have been anticipated by his views of its constitution. K. A. Hofmann and E. C. Marburg gave 4.083 for the sp. gr. at 18° . The salts of Millon's base are slowly decomposed when heated with potassium hydroxide, and they are scarcely soluble in 10 per cent. nitric, sulphuric, or acetic acid, and H. Gerresheim was able to crystallize salts of Millon's base from acetic acid soln. F. L. Sonnenschein, and E. Enss showed that ethyl iodide reacts with the salts of Millon's base, forming primary amines.

§ 9. Mercurous Fluoride

Mercury forms two fluorides—mercurous fluoride, HgF ; and mercuric fluoride, HgF_2 . J. L. Gay Lussac and L. J. Thénard¹ reported in 1811 that hydrofluoric acid does not react with mercury at any temp.; and J. J. Berzelius said that if hydrofluoric acid be added to a soln. of mercurous nitrate, no signs of precipitation occur, and when the soln. is evaporated, the hydrofluoric acid volatilizes leaving the original nitrate as a residue. H. Moissan found that mercury absorbs fluorine at ordinary temp., forming pale yellow mercurous fluoride; he also said that the same salt is formed by the action of fluorine on moderately heated mercuric oxide, but no evidence was advanced as to the purity of the product. J. J. Berzelius obtained mercurous fluoride by double decomposition by heating an intimate mixture of mercurous chloride and sodium fluoride in a matrass; the sublimate of mercurous fluoride must have been contaminated with chloride. J. J. Berzelius did not succeed in making mercurous fluoride by heating mercuric fluoride with mercury. R. Finkener prepared mercurous fluoride by adding freshly precipitated mercurous chloride to an excess of a soln. of silver fluoride: $\text{AgF} + \text{HgCl} = \text{AgCl} + \text{HgF}$, and on evaporating the clear liquid, small yellow crystals of mercurous fluoride appeared; he also prepared the same salt more readily by the action of hydrofluoric acid on recently precipitated mercurous carbonate. Hydrofluoric acid attacks mercurous oxide very slowly.

Mercurous fluoride forms pale yellow crystals—possibly cubic—which are stable in dry air and which can be heated to about 260° without change, but at higher temp. the salt sublimes, and the glass containing vessel is simultaneously etched. H. Moissan says that when heated in glass vessels, mercury and silicon tetrafluoride are formed. If exposed to humid air, or to light, the crystals are blackened. According to R. Finkener, the salt is partially decomposed by water into mercurous oxide and hydrofluoric acid, and part seems to dissolve as mercurous fluoride. J. J. Berzelius probably made an impure mercurous fluoride, for he stated the salt is white and insoluble in water. Mercurous fluoride dissolves in nitric acid, and the salt is precipitated from its soln. in dil. hydrofluoric acid by “salting” with potassium fluoride; the precipitate retains some acid potassium fluoride, KHF_2 , very tenaciously, and this salt can be removed only by prolonged washing. Mercurous fluoride is blackened by ammonia gas, forming what R. Finkener thought to be **mercurous ammino-fluoride**, $\text{HgF} \cdot \text{NH}_3$, which gives off ammonia at 100° . The addition of potassium hydroxide to a soln. of mercurous fluoride in hydrofluoric acid precipitates a black-coloured oxide. Mercurous fluoride gradually absorbs dry ammonia gas—the absorption of 7.63 per cent. occupied two days. The product is black. Aqua ammonia also gives a black precipitate which becomes grey on standing some time. The black precipitate is probably a mixture of mercuric oxide and mercury, and not as was once supposed *mercurous ammino-fluoride*, $\text{HgF} \cdot \text{NH}_3$, for as R. Finkener showed: (i) nitric acid develops nitric oxide and forms mercurous nitrate, leaving white mercuric oxide as a residue, and if dry mercurous fluoride be vigorously agitated with aqua ammonia, dil. nitric acid removes about half of the employed mercury; (ii) if ammonia be added to a dil. soln. of mercurous fluoride in hydrofluoric acid, but not to neutralize completely

the acid, the filtered liquid furnishes mercuric oxide, and the precipitate when dried in darkness at ordinary temp. contains metallic mercury. E. Böhm obtained colourless, prismatic monoclinic crystals of **mercurous hydrofluoride**, $\text{HgF}_2 \cdot 2\text{HF} \cdot 2\text{H}_2\text{O}$, with axial ratios $a : b : c = 0.5673 : 1 : 1.060$, and $\beta = 105^\circ 10'$, by dissolving freshly precipitated and well-washed mercuric oxide in hot conc. hydrofluoric acid, and evaporating the filtrate in vacuo over sulphuric acid. The crystals are fairly stable in dry hydrofluoric acid, and less stable over sulphuric acid in vacuo. When heated to redness, mercurous fluoride decomposes without melting, forming mercuric oxide and hydrogen fluoride. The crystals are hygroscopic in moist air; and they become white and opaque. The salt is soluble in water and dilute acids; the aq. soln. is blackened by alkali-lye; and, according to J. Philippi, it gives a white precipitate of mercuric thiocyanate, $\text{Hg}(\text{SCy})_2$, with potassium thiocyanate.

§ 10. Mercuric Fluoride

J. L. Gay Lussac and L. J. Thénard,¹ and J. J. Berzelius prepared a pale orange-yellow powder by the action of hydrofluoric acid on mercuric oxide. The powder dissolves in water, forming a colourless soln. which, on evaporation, furnishes dark yellow prisms which were thought to be crystals of mercuric fluoride. E. Frémy also obtained colourless needle-like crystals of a hydrated mercuric fluoride from the soln. obtained by the action of conc. hydrofluoric acid on mercury. In all these cases, R. Finkener believed that not mercuric fluoride, but rather **mercuric oxyfluoride**, $\text{HgO} \cdot \text{HgF}_2 \cdot \text{H}_2\text{O}$, or $\text{Hg}(\text{OH})\text{F}$, is formed. This compound does not change at 100° , but at a higher temp. the product darkens and gives off moisture and hydrofluoric acid which attacks glass; the compound finally melts and furnishes mercury. The oxyfluoride resembles mercurous fluoride in its action on water; it is soluble in dil. nitric acid.

According to O. Ruff and G. Bahlau, if mercurous fluoride or mercuric chlorofluoride—*vide infra*—be heated in chlorine to 275° , mercuric chloride sublimes, and anhydrous mercuric fluoride remains. Similarly, if mercurous fluoride or mercuric bromofluoride be heated in a stream of bromine at 400° , mercuric bromide sublimes and anhydrous mercuric fluoride remains, but in this case a loss of mercuric fluoride by sublimation occurs. If mercurous fluoride be heated at 450° and 10 mm. press., transparent octahedral crystals of anhydrous mercuric fluoride are formed.

According to R. Finkener, **dihydrated mercuric fluoride**, $\text{HgF}_2 \cdot 2\text{H}_2\text{O}$, can be made by the action of a large excess of 50 per cent. hydrofluoric acid on dry mercuric oxide. The product is a white solid contaminated with a little mercuric oxide. It is soluble in dil. nitric acid. When the solid is dehydrated it loses hydrofluoric acid, and either a mixture of mercuric oxide and mercuric fluoride or oxyfluoride, is formed. This salt is not altered by exposure to dry air or to light. Mercuric fluoride is largely hydrolyzed in aq. soln.: $\text{HgF}_2 + \text{H}_2\text{O} \rightleftharpoons \text{HgO} + \text{H}_2\text{F}_2$. A. Jäger

and A. J. Cox found the solubilities of mercuric oxide in hydrofluoric acid of different conc. to be :

TABLE IX.—HYDROLYSIS OF MERCURIC FLUORIDE.

Normality of hydrofluoric acid.	Gram atoms mercury per 1000 c.c.		Ratio found: Calculated.
	Found.	Calculated.	
0.12	0.01258	0.06	0.21
0.24	0.0247	0.12	0.20
0.57	0.0629	0.285	0.22
1.11	0.1168	0.555	0.21
1.14	0.1197	0.568	0.21
2.17	0.2586	0.185	0.24

The calculated value is based on the assumption that HgO is eq. to H_2F_2 . A. Jäger found the solubility of mercuric oxide in hydrofluoric acid to be lowered in the presence of potassium fluoride, owing to the decrease in the conc. of the acid by the formation of KHF_2 . R. Abegg and A. J. Cox estimate the ionization constant of mercuric fluoride: $\text{HgF}_2 = \text{Hg}^{++} + \text{F}_2^{--}$, to be about 260 times as great as the unknown ionization constant of hydrofluoric acid: $\text{H}_2\text{F}_2 = 2\text{H}^+ + \text{F}_2^{--}$.

A. J. Cox found that in the system: mercuric oxide, hydrofluoric acid, and water, as the conc. of the acid diminishes, the composition of the soln. remains constant, while the composition of the precipitate varies. Under these conditions, two solid phases are present—a mixture of mercuric oxide and fluoride—but the analyses give no indication of the presence of a basic mercuric fluoride. At 25° the minimum conc. of the hydrofluoric acid necessary for the existence of mercuric fluoride in soln. is 1.14*N*-HF. This shows that quite apart from the conc. of the acid, the yield of salt is only 0.22 of the theoretical, consequently, about 78 per cent. of the salt is hydrolyzed. This illustrates the difficulty, nay the impossibility—as C. Poulenc expresses it—of preparing anhydrous mercuric fluoride in the wet way.

O. Ruff and G. Bahlau's anhydrous mercuric fluoride forms transparent octahedral crystals of sp. gr. 8.95 (15°); m.p. 645°; and boiling point 650° (estimated). Attempts to determine the vapour tension at various temp. did not yield satisfactory results, since the vessels are attacked by the vapours. The substance is very sensitive to moisture and becomes discoloured by traces of water vapour, which are not analytically demonstrable; on exposure to air, hydrogen fluoride is evolved, and mercuric oxyfluoride and, ultimately, mercuric oxide remain. With small quantities of water, a white, hydrated oxyfluoride, $\text{Hg}_3\text{F}_4(\text{OH})_2 \cdot 3\text{H}_2\text{O}$, is formed, whilst with larger quantities, mercuric oxide is gradually produced. Mercuric fluoride dissolves in 40 per cent. hydrofluoric acid soln., and, on cautious evaporation, R. Finkener's dihydrated fluoride, $\text{HgF}_2 \cdot 2\text{H}_2\text{O}$, is obtained in small, colourless crystals. The vapours of mercuric fluoride attack platinum above 500°; mixtures of the fluoride with silver, copper, lead, aluminium, magnesium, zinc, tin, chromium, iron, or arsenic react vigorously when strongly heated locally, yielding

FIG. 10.—Relation between Composition of the Precipitate and of the Solution at 25°.

amalgams and metallic fluorides, the latter being easily obtained in a high degree of purity, if an excess of mercuric fluoride is used. Sulphur tetrafluoride appears to be formed when mercuric fluoride is heated with sulphur, but no reaction occurs with amorphous or graphitic carbon. The fluorine does not appear to be replaced when mercuric fluoride is heated in a stream of chlorine or bromine. However, if dry chlorine be passed over mercurous fluoride at 120° , O. Ruff and G. Bahlau said that pale yellow **mercuric fluochloride**, HgClF , is formed; and with bromine at 105° pale yellow **mercuric fluobromide**, HgFBr . H. Moissan made the former compound by passing a current of dry chlorine over the product obtained by heating E. Frémy's $\text{HgF}_2 \cdot 2\text{H}_2\text{O}$ to 350° , and drying by contact with anhydrous hydrofluoric acid.

E. Böhm prepared the fluorine analogue of infusible white precipitate (*q.v.*) with the composition $\text{HgF} \cdot \text{NH}_3$, and which E. C. Franklin called **mercuric fluoroamide**, $\text{NH}_2\text{—Hg—F}$, or $\text{Hg}(\text{NH}_2)\text{F}$, by mixing 200 grms. of conc. hydrofluoric acid with an excess of yellow mercuric oxide, and adding an excess of ammonia to the filtered soln. A pale yellow amorphous powder separated when alcohol was added. This was washed with alcohol and ether, and dried over sulphuric acid in vacuo in darkness. When exposed to light the surface of the powder is coloured grey, owing to the separation of mercury; it is insoluble in water, and in nitric and sulphuric acids, but is readily soluble in dil. hydrochloric acid. When heated in a tube, it sublimes with partial decomposition.

R. Finkener reported the formation of a white pulverulent compound, $\text{NHg}_2\text{F} \cdot \text{HF} \cdot \text{H}_2\text{O}$, by the addition of a small excess of ammonia to a soln. of mercuric fluoride in hydrofluoric acid; on standing in the cold a white gelatinous mass separates gradually—rapidly when heated—it can be washed without decomposition, and dried over sulphuric acid. On the ammonium theory, the compound is called *oxydimercuri-ammonium fluoride*, and represented $\text{NH}_2(\text{Hg} \cdot \text{O} \cdot \text{Hg})\text{F} \cdot \text{HF}$, while in E. C. Franklin's nomenclature it is **mercuric difluoroamide**, $(\text{HgF})_2\text{NH} \cdot \text{H}_2\text{O}$. According to R. Finkener, when heated with lead oxide in a glass tube to about 200° , this compound decomposes: $6\text{PbO} + 6(\text{NHg}_2\text{F} \cdot \text{HF} \cdot \text{H}_2\text{O}) = 6\text{PbF}_2 + 9\text{HgO} + 3\text{Hg} + 3\text{H}_2\text{O} + 4\text{NH}_3 + \text{N}_2$.

§ 11. Mercurous Chloride

Mercury forms two chlorides, calomel or mercurous chloride, HgCl , and corrosive sublimate or mercuric chloride, HgCl_2 . Both appear to have been known under various names for quite a long time, although the discoverer of either is unknown. A. M. Rhases mentioned corrosive sublimate in the tenth century, and E. S. Avicenna in the eleventh century. We are also told that it was known to the Chinese. H. Kopp, in his *Geschichte der Chemie* (Braunschweig, 1847), has reviewed the history of the mercury chlorides. In the thirteenth-century works of the Latin Geber, *De inventione veritatis*, and of Albertus Magnus, *Compositum de compositis*, there are descriptions of a method of preparing *album sublimatum*, by sublimation in an aludel, from an intimate mixture of mercury, rock alum, common salt, and saltpetre. The—presumably—sixteenth- or seventeenth-century works of Basil

Valentine have also much to say on the preparation of *mercurius sublimatus*, and at that time it appears to have been an article of commerce. Since mercurous chloride is formed if mercury be in excess, the older preparations must frequently have been mixtures of both mercury chlorides, and the term was for some time applied to these two salts. The corrosive properties of mercuric chloride led to its being called *draco, mors metallorum*, or *malleus metallorum* on account of its destroying, "deadening," or "sickening," the metallic lustre of many metals; it was also called *mercurous sublimatus corrosivus*, or simply *corrosive sublimate*. The old synonyms for the two mercury chlorides have been tabulated in G. F. Hildebrandt's *Chemische und mineralogische Geschichte des Quecksilbers* (Braunschweig, 1793).

Basil Valentine¹ mentions the preparation of *mercurius sublimatus* by sublimation from a mixture of vitriol, common salt, and mercury, and he says that during the operation, the spirit of salt (hydrochloric acid) unites with the mercury. N. Lemery described its preparation from mercury nitrate, common salt, and calcined vitriol; and O. Tachen (1666) gave a minute description of the process employed in Venice and in Amsterdam for the preparation of corrosive sublimate. J. Kunckel (1716) and G. F. Boulduc (1730) prepared the salt by sublimation from a mixture of mercury sulphate and common salt. A. G. Monnet (1771) made it in the wet way by mixing common salt with a soln. of a mercuric salt, or by cooling a hot soln. of mercury in a mixture of nitric and hydrochloric acids. Indeed, T. Bergman (1781) enumerated fourteen methods of preparing this salt. J. Beguin said that corrosive sublimate sublimes more rapidly and the product is denser if some arsenic be present. C. Glaser (1663), R. Boyle (1661), and N. Lemery (1675) also refer to the adulteration of corrosive sublimate with arsenic.

Mercurous chloride was used medicinally in the sixteenth century. It was sometimes designated *panchymachogum Quercetani*, *panchymachogum minerale*, *panacea mercurialis*, *panacea celestis*, etc. A. Libavius (1597) called it *aquila alba*, and J. Beguin (1608) and O. Croll (1609) called it *draco mitigatus*, or *manna metallorum*; F. Sylvius de la Bøe (1671), *mercurius dulcis*; and N. Lemery (1675), *sublimé doux*. From this it would appear as if the early impure preparations had a sweet taste, although the compound itself is tasteless. The term *calomel*—from *καλός*, good; and *μέλι*, sweet, in reference to its name *mercurius dulcis*; or from *καλός*, good; *μέλας*, black—possibly refers to the blackening which this salt suffers when treated with an alkali; to its use as a good remedy for black bile; or to the general regard for black mercury sulphide to which the name calomel was first applied.

O. Croll (1609), near the beginning of the seventeenth century, spoke of the secrecy and mystery of the process of preparing this salt, and J. Beguin (1608) referred to its preparation from *mercurius sublimatus*, mercury, and red oxide of iron. J. le Mort (1696) first mentioned its preparation from mercury, salt, and calcined vitriol, without *mercurius sublimatus*; and J. Zwelfer (1652) mentioned the purification of this salt by washing out the corrosive sublimate with water. In the fourteenth century, J. de Roquetaillade first described the preparation of calomel in the wet way as a precipitate by adding sal ammoniac to a soln. of mercury in nitric acid—the calomel was afterwards purified by sublimation—and N. Lemery (1675) used salt, or hydrochloric acid, and called the product *le précipité blanc*; H. Boerhaave (1732), *mercurius precipitatus albus*; and J. Kunckel (1716), *lac mercurii*. C. Neumann (1740) stated that the precipitate obtained in this way is the same as *mercurius dulcis* prepared by sublimation, and C. W. Scheele (1778) confirmed C. Neumann's hypothesis. This method of preparation is sometimes called Scheele's process. N. Lemery (1675) and J. C. Barchusen (1703) believed that the difference in the two mercury chlorides is due to the corrosive sublimate having united with more acid than is the case with calomel; and later, after the discovery of chlorine, the difference in the composition of the two salts was made clear. R. Chenevix first analyzed the two chlorides in 1802.

In 1776, P. Woulfe² discovered at Zweibrücken (Rhine Palatinate) a mineral,

horn mercury or *horn quicksilver*, to which M. Sage applied the term *mine de mercure cornée*, and concerning which J. B. L. Romé de l'Isle said: "*Mine de mercure cornée volatile*, or *mercure doux natif*, is mercury solidified and mineralized by muriatic acid . . . it appears to have been sublimed on the walls of the cavities in certain mines." At first, P. Woulfe, and R. Kirwan thought that horn mercury contains some sulphate, but R. J. Haüy regarded it as *le muriate de mercure des chimistes*. Horn mercury was shown by J. L. Proust, L. Gmelin, and C. F. Rammelsberg to be identical with mercurous chloride. The mineral is comparatively rare; it occurs in translucent tetragonal crystals as a secondary mineral. Specimens have been reported from the Palatinate, Lüneberg, and Gifftberg (Germany); Idria (Carniola); Avala (Serbia); Almaden (Spain); Montpellier (France); El Doctor (Mexico); Terlingua (Texas); Sarawak (Borneo), etc.

The preparation of mercurous chloride.—1. *By the action of chlorine or hydrogen chloride on mercury.*—R. Cowper³ found that chlorine attacks mercury energetically no matter whether the gas be moist or thoroughly dried, although W. A. Shenstone and C. R. Beck found the action is much slower when the gas is highly purified, and dry mercury burns with an orange flame when heated in chlorine gas, forming a mixture of mercury chlorides; at ordinary temp., C. E. Schafhäütl, and I. Bhaduri found mercurous chloride is formed if the metal be in excess, and similar remarks apply to the action of chlorine water. M. Berthelot said that in the presence of air, hydrogen chloride and mercury form mercurous chloride. He also stated that hydrogen chloride does not attack mercury in the cold, but in the presence of a little oxygen, mercurous chloride together with a little oxychloride are slowly formed; the speed of the reaction is favoured by moisture and the presence of alkali chlorides. G. H. Bailey and G. J. Fowler said that the oxychloride $\text{Hg}_2\text{OCl}_2 \cdot \text{H}_2\text{O}$ is formed in the reaction which "proceeds in the dark as well as when exposed to light, and indeed powerful sunlight seems, if anything, unfavourable to it." M. Berthelot added that hydrogen chloride does not attack mercury at 200° ; but if mercury be electrified in the presence of hydrogen chloride, hydrogen and mercurous chloride are formed.

C. E. Schafhäütl, and P. Süss say that mercury slowly reduces an aq. soln. of ferric chloride, and rapidly if the soln. be acidified with hydrochloric acid: $\text{FeCl}_3 + \text{Hg} = \text{HgCl} + \text{FeCl}_2$; and C. E. Schafhäütl studied the old process for preparing mercurous chloride by sublimation from an intimate mixture obtained by triturating mercury with sodium chloride, ferric sulphate or basic ferric sulphate and water, some ferric chloride is probably sublimed with the mercurous chloride: $\text{Fe}_2(\text{SO}_4)_3 + 6\text{NaCl} + 2\text{Hg} = 3\text{Na}_2\text{SO}_4 + 2\text{FeCl}_2 + 2\text{HgCl}$. P. L. Geiger recommended making mercurous chloride, by triturating two gram-atoms of mercury with two mols of sodium chloride, and one of manganese dioxide, and heating the mixture with two mols of sulphuric acid until the mercurous chloride sublimed: $2\text{Hg} + 2\text{NaCl} + \text{MnO}_2 + 2\text{SO}_3 = \text{Na}_2\text{SO}_4 + \text{MnSO}_4 + 2\text{HgCl}$. O. Henry, and J. Raab sublimed a mixture of mercury, mercuric sulphate, and salt: $\text{HgSO}_4 + \text{Hg} + 2\text{NaCl} = 2\text{HgCl} + \text{Na}_2\text{SO}_4$; or $\text{HgSO}_4 + \text{Hg} = \text{Hg}_2\text{SO}_4$; and $\text{Hg}_2\text{SO}_4 + 2\text{NaCl} = \text{Na}_2\text{SO}_4 + 2\text{HgCl}$.

2. *By the action of chlorides on mercurous salts.*—As shown by C. W. Scheele (1778), mercurous chloride is precipitated when an aq. soln. of a mercurous salt is treated with sodium chloride, and the precipitate washed with cold water. The mercurous chloride so obtained is a fine powder. J. A. Buchner, and L. Mailhe found that when mercurous nitrate is used, the precipitate is contaminated with basic mercurous and mercuric nitrates; but not if the mercurous nitrate be very dil., and the sodium chloride be added in excess, and the liquid be warmed with the precipitate for some time. With the same object, N. G. Sefström, P. L. Geiger, and J. B. Trautwein recommended using a soln. of mercurous nitrate acidified with nitric acid; and R. Chenevix, a soln. of sodium chloride acidified with hydrochloric acid. E. Schmidt's directions are:

A soln. of 10 parts of mercurous nitrate, 1.5 parts of nitric acid, and 88.5 parts of water is poured with constant stirring into a clear soln. of 3 parts of sodium chloride in 12 to 15

parts by weight of water. To avoid the formation of sparingly soluble basic mercurous nitrates, the sodium chloride is kept in excess by pouring the mercurous nitrate soln. into that of sodium chloride, not conversely. The precipitated mercurous chloride is allowed to settle away from light and the supernatant liquor poured off; it is stirred up with cold water, and the operation repeated until the wash liquor gives no turbidity with silver nitrate. The precipitate is collected on a filter and dried.

According to J. B. A. Dumas, the precipitate cannot be freed from sodium chloride by washing, and he says this explains why the precipitated salt is more soluble than the sublimed; but L. Mailhe said that only a small trace of sodium chloride is retained by the precipitate, and the solubilities of the sublimed and precipitated salts are the same. The precipitated salt in the finer state of subdivision may dissolve more quickly than the sublimed salt. T. Martius recommended using ammonium chloride in place of sodium chloride, but there is then a difficulty in removing the ammonia from the precipitate, and F. J. Otto does not recommend the process, although M. Fleischmann says that the whole of the ammonia can be removed from the precipitate by a prolonged washing with cold water. N. J. B. G. Guibourt precipitates mercurous chloride by adding hydrochloric acid to a conc. soln. of a mercurous salt; L. Gmelin says that heating should be avoided, and that a dil. soln. gives better results. R. Varet recommends precipitating with a soln. of potassium chloride, and, after washing, drying in darkness at 110° . W. Sievers passed chlorine into a feebly acid conc. soln. of mercurous nitrate and washed the mixture of mercurous and mercuric chlorides with hot water to remove the mercuric chloride. The precipitate was dissolved for a long time with a boiling soln. of mercurous nitrate; and the crystals which separated from the cooling soln. were washed first with nitric acid, and then with water. H. Debray first showed that lustrous crystals are deposited from a soln. of calomel in one of hot mercurous nitrate. Mercurous chloride is also formed, when mercurous oxide is treated with hydrochloric acid. L. A. Planché prepared mercurous chloride by sublimation from an intimate mixture of mercurous sulphate and sodium chloride. The directions in the British Pharmacopœia are:

Moisten 10 parts of mercuric sulphate with some water and rub it with 7 parts of mercury until globules are no longer visible; add 5 parts of sodium chloride and thoroughly mix the whole by continued trituration. When dry, sublime in a suitable apparatus into a chamber of such a size that the calomel, instead of adhering to its sides as a crystalline crust, shall fall as a fine dull white powder on its floor. Wash this powder with boiling distilled water until the washings cease to be darkened with ammonium sulphide. Finally, dry at a heat not exceeding 100° , and preserve in a jar or bottle impervious to light.

Sublimed calomel condenses as a dense fibrous mass which requires pulverization before use; as in the manufacturing process when, for medical purposes, the calomel is required in a fine state of subdivision. E. Soubeiran and F. C. Calvert recommended carrying the vapour of the subliming calomel by means of a stream of cold air, into a large chamber where the salt was condensed. J. Jewel, and O. Henry proposed a stream of steam instead of air. G. Lunge and E. Divers have described how calomel—*keifun*—free from corrosive sublimate is made in Japan:

Balls of porous earth and salt—from the bittern of partially evaporated sea-water—are heated along with mercury in iron pots with earth. The magnesium salts derived from the bittern, together with the air which diffuses into the pots, form hydrogen chloride, and this reacts with the mercury which sublimes into the clay covers of the pots: $4\text{Hg} + 4\text{HCl} + \text{O}_2 = 4\text{HgCl} + 2\text{H}_2\text{O}$, so that the covers become filled with a network of micaceous scales of white or pale cream-coloured calomel.

3. *By the reduction of mercuric chloride.*—As known to the alchemists, mercurous chloride can be prepared by the reduction of mercuric chloride, say, by trituration it with mercury, and heating the mixture until it sublimes. A great deal of the mercuric chloride is reduced during the trituration. J. B. Trautwein warmed the mixture for some hours and again trituated it before sublimation.

On a large scale, 17 parts of corrosive sublimate are mixed with a little alcohol or water, and rubbed up with 13 parts of mercury until the metal is "deadened." The mixture is

then sublimed in glass flasks. The calomel condenses in the upper cooler part of the flask as a solid, translucent, fibrous cake. The flasks are broken, and the cake removed. The cake is ground to powder and washed repeatedly with boiling water.

G. F. Hildebrandt said that the alchemists used to repeat the sublimation a number of times, for they refer to calomel six or seven times re-sublimed, and to *panacea mercurialis* re-sublimed nine times.

F. Wöhler reduced mercuric to mercurous chloride, by digesting a sat. aq. soln. of mercuric chloride and *sulphur dioxide* at 50° for some time, and washing the precipitated mercurous chloride. According to A. Vogel, the reduction is complete only with a large excess of sulphur dioxide frequently renewed. J. Zinkeisen, and F. Muck employed a sat. soln. of mercuric chloride above 75°, below this temp. the reaction is not complete. W. Stein, and F. Sartorius emphasized the use of dil. mercuric chloride soln. (say, 1 : 80) at 70° to 80° under which conditions the reduction is almost quantitative; indeed, D. Vitali employed the reaction for the determination of mercuric chloride. R. Wagner recommended treating an alcoholic soln. of mercuric chloride with sulphur dioxide. H. Rose treated the mercuric chloride soln. with boiling *ammonium sulphite* (if cold, there is no appreciable reduction, and if the boiling be prolonged, P. Berthier says the calomel is partly reduced to mercury); J. Meyer recommended warm *lithium sulphite*; H. Rose reduced mercuric chloride soln. with *hypophosphorous acid* (when the mercuric chloride is in excess, otherwise mercury is precipitated); and C. Glücksmann used an excess of *barium hypophosphite* in the presence of hydrochloric acid, and found the reaction quantitative; W. Hempel reduced mercuric chloride with *ferrous sulphate*; T. Fairley, with *hypochlorites*; N. A. E. Millon, with *potassium hydrogen oxalate*; and J. Schoras, and W. Uloth, with *oxalic acid*. J. M. Eder exposed a mixture of mercuric chloride and oxalic acid to sunlight; P. A. von Bonsdorff reduced mercuric chloride with *formic acid*; F. W. O. de Coninck and M. Dautry, with *malonic acid*; and P. Duret with *dextrose*. The last-named claimed by the following process to prepare a fine-grained, light, and voluminous form of calomel with greater germicidal powers than the ordinary preparations when used in prophylactic ointments, or anti-syphilitic injections:

A soln. containing 5 grms. of sodium hydrogen carbonate and 10 grms. of dextrose in 80 c.c. of water is added to a soln. containing 7.5 grms. of crystalline magnesium chloride in 20 c.c. of water, and this mixture is added to a soln. containing 11.5 grms. of mercuric chloride and ten drops of hydrochloric acid in 100 c.c. of water in a flask. When the reaction has ceased, the mixture is heated on a water-bath until all the carbon dioxide is evolved. The finely divided precipitate of mercurous chloride is then collected and washed with water.

M. Gambier claimed to have made still more active calomel by varying the precipitating and reducing agents.

J. H. Gladstone and A. Tribe reduced mercuric chloride by dipping a plate of platinum or gold in a soln. of mercuric chloride, and connecting it electrically with mercury, also in contact with the same soln. F. Paschen, and A. W. Laubengayer, noted the formation of mercurous chloride at the surface of a mercury anode in hydrochloric acid, etc.

When a sample of dry mercurous chloride is heated in a test-tube it should volatilize completely without giving off acid fumes. If the calomel were adulterated with powdered barytes, etc., this would remain as a non-volatile residue; and if mercurous or mercuric nitrate were present, fumes of nitrogen peroxide would be evolved. Adulterations with gum or other organic matters are detected by the smell when heated. The aq. extract of the salt when filtered and evaporated to dryness should give no residue showing the absence of soluble salts, and the aq. extract should not give a white turbidity with stannic chloride soln. showing the absence of mercuric chloride. E. F. Anthon recommended extracting with ether or alcohol. According to H. Bonnewyn, if a clean knife-blade be immersed in the calomel moistened with alcohol or water, a black spot may be formed on the blade

if as little as 2×10^{-5} parts of mercuric chloride be present. Mercury may be detected by the microscope, or by shaking the calomel with nitric acid diluted with its own vol. of water when any metallic mercury will be dissolved. The filtrate is then tested for mercury by hydrogen sulphide, etc.

A. Lottermoser⁴ found that if chlorine water be added to a soln. of colloidal mercury, the liquid becomes milky or turbid and **colloidal mercurous chloride** is formed—if an excess be added, colloidal mercuric chloride is formed. E. von Meyer and A. Lottermoser also added a soln. of mercuric chloride to colloidal silver and obtained a milky hydrosol of mercurous chloride. A. Gutbier also prepared the same hydrosol by adding hydroxylamine hydrochloride to a soln. of a mercurous salt, or hydrazine hydrate to a very dil. soln. of mercuric chloride. The Chemische Fabrik von Heyden patented the following process:

Dissolve 100 parts of sodium lysalbinat in 4000 parts of water, and add a soln. of 40 parts of sodium chloride in 2000 parts of water, and then a soln. of 120 parts of mercurous nitrate in 4000 parts of water. When an acid is added, the precipitate which is obtained can be washed with water. The precipitate is soluble in a very dil. soln. of alkali, and the soln. can be evaporated to dryness.

The white solid forms a milky fluid with water 1:50; it is insoluble in alcohol, ether, benzene, and chloroform. H. Lachs studied the scintillation of mercurous chloride as an ultramicroscopic colloid, and found that the effect diminishes with long standing owing to the development of long crystals.

The properties of mercurous chloride.—The crystals of the natural product occur in bipyramids belonging to the tetragonal system with the axial ratio, according to J. Schabus,⁵ $a:c=1:1.7356$; W. F. Hillebrand and W. T. Schaller give $a:c=1:1.7232$. The product obtained by sublimation is a compact crystalline mass unless precautions are taken to keep the product pulverulent—the Japanese product is in micaceous crystals. The precipitated salt is usually a white powder. A soln. of mercurous chloride in a hot soln. of mercurous nitrate, as indicated previously, gives crystals with a mother-of-pearl lustre. H. Behrens obtained needle-like crystals from a soln. of mercurous nitrate and hydrochloric acid. E. Mitscherlich, and W. J. Luczizky obtained from ethyl and methyl alcohol soln. rhombic crystals with axial ratios $a:b:c=0.7251:1:1.069$; and the latter also obtained a second rhombic form, so that this compound appears to crystallize in three different forms—see mercuric bromide. The **specific gravity** of native mercurous chloride by W. Haidinger⁶ is 6.482; and the reported numbers for artificial crystals vary from the 6.56 of H. Schiff to the 7.178 of L. Playfair and J. P. Joule. According to J. Meyer, the lustrous scales prepared from mercuric chloride and lithium sulphite have a sp. gr. 4.5 to 5.0, but show no difference of potential against ordinary mercurous chloride in a galvanic cell, and in consequence do not appear to be an allotropic modification of the latter. A. Reis and L. Zimmermann gave 2.6 for the **hardness**.

The **specific heat** of mercurous chloride, measured by A. Magnus⁷ between 15° and 100° is 0.05296; and the **molecular heat**, 12.48 ± 0.065 . H. V. Regnault gives 0.05205 for the sp. ht. A. Eucken showed that the mol. heat decreases as the temp. is reduced, being 11.43 at 17.5°; 10.70 at -67.5°; and 9.46 at -168.2°; and, according to F. Pollitzer, the mol. ht. of crystalline mercurous chloride falls from 11.51 at -74° to 8.44 at -199.5°; and, for the pulverulent salt, from 9.03 at -184° to 8.79 at -190°. E. Jannetaz gives 0.77 for the square root of the ratio of the **heat conductivities** of mercurous chloride crystals in the direction of the chief axis and in the direction of the base. T. Carnelley gives for the **melting point** 302°, but, as W. Hampe showed, in open vessels, it vaporizes without melting. M. Faraday obtained no signs of vaporization at ordinary temp., but C. Zenghelis placed mercurous chloride 5 cms. above a silver plate for a month, and found that the silver was attacked—presumably by the vapour of the calomel. H. Arctowsky heated calomel to different temp. for 5 hrs. and measured the loss of weight; he found at 86.5° a loss of 0.005 grm.; at 98.5°, 0.0013 grm.; at 120.25°, 0.0025 grm.;

at 152° , 0.014 grm.; and at 175.25° , 0.058 grm. M. Berthelot noted a perceptible volatilization at 250° . W. P. A. Jonker gives the **sublimation point** as 373° ; A. Smith and A. W. C. Menzies say the **boiling point** at atm. press. is 382.5° ; A. Smith and R. P. Calvert, 383.7° ; W. P. A. Jonker, 373° ; and W. Harris and V. Meyer give 357° . J. C. G. de Marignac gives the **latent heat of vaporization** per gram 131 cal. at 16° ; 127 cal. at 18° . A. Smith and R. P. Calvert found that the **entropy of vaporization** of mercurous chloride corresponds with the value for associated liquids; by Trouton's rule, 18.7; and by Hildebrand's rule, 17.7 for a conc. 0.005 mol per litre.

The **vapour pressure** of mercurous chloride in equilibrium with the solid below 180° was determined by E. Wiedemann, K. Stelzner, and G. Niederschulte, and by A. Smith and A. W. C. Menzies for temp. exceeding 360° . The vapour press. p mm. of mercury at θ° is:

θ	.	.	90°	110°	150°	170°	180°	360°	370°	380°	390°	400°
p	.	.	0.004	0.011	0.07	0.27	0.45	434	556	712	906	1135

The salt carefully dried over phosphorus pentoxide gives no appreciable vap. press. after being held for 15 mins. at 352° .

Determinations of the **vapour density** of mercurous chloride by E. Mitscherlich,⁸ H. St. C. Deville and L. Troost, and R. Rieth show but half the value calculated for Hg_2Cl_2 . For example, the vapour density of mercuric chloride at 518° is 235.5 ($\text{O}_2=32$). This number agrees with 235.5 required for the simple mol. HgCl . If mercury be a dyad, and if it has a constant unchangeable valency, the formula should be Hg_2Cl_2 , that is, $\text{Cl}-\text{Hg}-\text{Hg}-\text{Cl}$. In that case, the observed vapour density means that the mercurous chloride dissociates into mercuric chloride and mercury: $\text{Hg}_2\text{Cl}_2=\text{Hg}+\text{HgCl}_2$, the theoretical vapour density of which is $\frac{1}{2}(200+270.9)=235.5$, the same as for HgCl . The vapour density determination does not therefore furnish a definite answer to the obvious question.

W. Odling showed that calomel vapour amalgamates gold-leaf, and hence inferred that probably some mercury is present. J. C. G. de Marignac also deduced from the latent heat of vaporization that *s'il y a commencement de dissociation, il est au moins extrêmement limité*. H. Debray could find no amalgamation at 400° , but H. B. Baker obtained it at 445° . E. Erlenmeyer obtained a very small proportion of free mercury in a deposit of sublimed calomel; and H. Debray obtained free mercury by rapidly cooling the vapour by a gilded silver tube cooled by running water. All these experiments show that probably free mercury vapour is present in calomel vapour, although it might be argued that gold-leaf decomposes the vapour of calomel. At best, the preceding experiments show that some dissociation occurs, whereas the observed vapour density requires almost complete dissociation. The argument based on the constant valency of mercury is of no value. H. B. Baker claimed that the vapour density of calomel, perfectly dry, corresponds with the formula Hg_2Cl_2 as shown (a) by the vapour density, and (b) by the absence of the amalgamation with gold, but if the calomel be not so completely dried, it is probable that Hg_2Cl_2 dissociates into Hg and HgCl_2 , analogous with the behaviour of perfectly dried ammonium chloride, which is known to behave in this manner. H. Debray argued that the decomposition cannot be complete because the condensation of the vapour yields mercurous and mercuric chlorides as well as mercury. According to W. Harris and V. Meyer, gold-leaf is amalgamated at the moment when it is inserted in the calomel vapour, but on becoming hot, the gold amalgam is dissociated and the colour of the gold is restored. W. Harris and V. Meyer attempted to determine the amount of dissociation. They heated calomel to 465° in a wide glass tube containing a narrower porous vessel. They obtained a "dense mass" of mercury (with the heavier vapour) in the wider tube, and a "considerable amount" of corrosive sublimate in the inner cell, and hence said that this result proves a copious dissociation of the calomel vapour. The conclusion is a *non sequitur* because the removal of a small proportion of one product of dissociation

would disturb the equilibrium, and in accord with the law of mass action would liberate far more mercury than would be represented by the actual amount of dissociation in the undisturbed vapour. W. Harris and V. Meyer then assumed that a vapour largely composed of mercurous chloride should give the reactions of a mercurous salt while one composed largely of mercury and mercuric chloride should give the reactions of a mercuric salt. They show that a rod of solid potassium hydroxide at 240° – 260° , when immersed in the vapour of calomel in another tube at the same temp., is immediately covered with a layer of red mercuric oxide just as occurs with the vapour of mercuric chloride, and although mercurous oxide is unstable at this temp., W. Harris and V. Meyer assumed that their experiment would have shown its presence as a transient intermediate compound if mercurous chloride vapour had been present. They also say that the mercuric oxide was not formed by the decomposition of the mercurous oxide, because a stick of potash coated with mercurous oxide forms no perceptible mercuric oxide in 15–25 secs. The conclusion that the mercuric oxide could not have arisen from previously formed mercurous oxide, but is a direct product of the interaction with the vapour from calomel is probably correct, because there is no particular reason for assuming that mercurous oxide would be formed under these conditions if the vapour really contained mols. of mercurous chloride. There is no justification in these results for the sweeping conclusion that "calomel vapour decomposes completely according to the equation: $\text{Hg}_2\text{Cl}_2 = \text{HgCl}_2 + \text{Hg}$." In a controversy with V. Meyer, M. Fileti claimed that the vapour density of calomel in the presence of the vapour of mercuric chloride corresponds to HgCl , not Hg_2Cl_2 , and that there is no dissociation because gold-leaf (cooled by water) is not amalgamated. In fine, none of these qualitative experiments can give a quantitative idea of the proportion of dissociated— $\text{Hg} + \text{HgCl}_2$ —to undissociated— HgCl —mols. in calomel vapour.

A. Smith and A. W. C. Menzies calculated the vap. press. of calomel on the extreme assumptions that there is no dissociation, and that there is complete dissociation. The vap. press. of a mixture of calomel and mercury will be equal to the sum of the vap. press. of mercury and calomel, if there be no dissociation, and less than this sum if dissociation of the calomel vapour occurs. Experiment showed that the observed vap. press. of the mixture is less than that calculated for complete dissociation. This was traced to a slight lowering of the vap. press. of mercury owing to its dissolving a little calomel. Allowing for this, A. Smith and A. W. C. Menzies' measurements give numbers in close agreement with the view that the vapour of calomel is completely dissociated, and that mols. of the types HgCl and Hg_2Cl_2 are not present in the sat. vapour of calomel.

A. Smith and R. P. Calvert have determined the **dissociation pressures** of calomel vapour and find at 309.52° , the dissociation press. is 103 mm.; at 341.56° , 261.4 mm.; at 367.72° , 522.5 mm.; and at 383.95° , 764.7 mm. If p denotes the press. in mm. of mercury at the absolute temp. T° , the observed results can be very well represented by the formula: $\log p = -7792.10T^{-1} - 12.2309 \log T + 49.2048$. According to A. Smith and A. W. C. Menzies, the lowering of the vap. press. of mercury by the soln. of calomel between 360° and 400° corresponds with the **molecular formula** HgCl ; and, according to E. Beckmann, the lowering of the f.p. of mercuric chloride by the soln. of mercurous chloride agrees with the formula Hg_2Cl_2 .

T. Andrews⁹ first measured the heat disengaged during the combination of mercury with chlorine, and he says, "The primary compound formed in this reaction is probably HgCl_2 , but by the action of the excess of mercury a portion is afterwards converted into the subchloride Hg_2Cl_2 ." According to R. Varet, the **heat of formation** of mercurous chloride from liquid mercury and chlorine gas is ($2\text{Hg}, \text{Cl}_2$) = 62.65 Cals. W. Nernst gives 62.6 Cals.; J. Thomsen, 62.55 Cals. According to M. de K. Thompson, the **free energy of formation** at 18° , with chlorine at atm. press., is -49.4 Cals., or with respect to liquid chlorine, -50.0 Cals., or calculated from the solubility of mercurous chloride, -52.1 Cals.; and the **total energy** is

between -57.6 and 62.0 Cals. J. Thomsen gives for $\text{Hg}_2(\text{NO}_3)_{2\text{aq.}} + 2\text{KCl}_{\text{aq.}} = 24.32$ Cals.; and for $\text{Hg}_2\text{O} + 2\text{HCl}_{\text{gas}} = 64.71$ Cals. M. Berthelot gives for the $\text{Hg}_2\text{Cl}_2 = \text{HgCl}_{2\text{solid}} + \text{Hg}_{\text{liquid}} - 19$ Cals. R. H. Gerke gave for the entropy change at 25° , $\text{Hg} + \frac{1}{2}\text{Cl}_2 = \text{HgCl} - 21.8$.

The crystals have a positive double refraction, and A. des Cloizeaux¹⁰ says the **indices of refraction** for the red ray are $\omega = 1.96$, and $\epsilon = 2.60$; while H. Dufet gives for the Li-line, $\omega = 1.9556$, and $\epsilon = 2.6006$; for the Na-line, $\omega = 1.97325$, and $\epsilon = 2.6559$; and for the Tl-line, $\omega = 1.99085$, and $\epsilon = 2.7129$. W. Haidinger says the sublimed crystals from Schmölnitz are pleochroic, for the ω -ray is pale wine yellow and the ϵ -ray reddish-brown. J. A. Wilkinson says the crystals have an orange fluorescence, and O. Wolff that they exhibit an orange **luminescence** in ultra-violet light, but no thermo-luminescence. A. L. Hughes has shown that mercurous chloride gives a well-marked **photoelectric effect**. E. J. Evans studied the **absorption spectrum** of mercurous chloride vapour.

According to V. von Lang,¹¹ mercurous chloride is diamagnetic. C. Fritsch found the **electrical conductivity** of a plate of pressed powder increases from 31 to 130 mhos when mixed with 1 per cent. of sodium chloride, and to 1700 with 2 per cent. of sodium chloride. W. Hampe says the molten salt conducts electrolytically. E. Rothe gives the **electromotive force** of the calomel electrode as 0.56 volt. R. Behrend found the e.m.f. of the cell $\text{Hg} | \text{HgCl}, \frac{1}{10}N\text{-KCl} | \frac{1}{10}N\text{-HgNO}_3, \text{HNO}_3 | \text{Hg}$ to be 0.391 volt; A. Ogg for the same cell with $N\text{-HNO}_3$ and $N\text{-KCl}$ found 0.466 volt; H. Ley and C. Heimbucher, for the cell $\text{Hg} | \text{HgCl}, \frac{1}{10}N\text{-KCl} | \frac{1}{10}N\text{-HgClO}_4 | \text{Hg}$, 0.420 volt (20°); and for the same cell with $\frac{1}{100}N\text{-KCl}$, 0.472 volt. The conc. of the ions Hg_2^{++} in the sat. calomel soln. calculated from the e.m.f. of these cells are respectively 1.6×10^{-6} ; 1.0×10^{-6} ; 0.72×10^{-6} ; and 0.79×10^{-6} . L. S. Bagster and B. D. Steele gave for the cell $\text{Hg} | \text{HgCl}, \text{SO}_{2\text{liquid}} | \text{SO}_2 | \text{PbCl}_2, \text{SO}_{2\text{liquid}} | \text{Pb}$, 0.43 volt. R. Luther also showed that the grain-size of the calomel exercises an important influence on the e.m.f. A. W. Laubengayer has shown that the apparent polarization of the calomel electrode is probably due to the formation on the surface of the mercury anode, of a strongly adsorbed film of mercurous chloride which offers a high resistance to the passage of the current. The calomel cell has been studied by H. A. Fales and W. A. Mudge, S. Bodforss, etc. W. R. Hainsworth and D. A. MacInnes measured the effect of press., p , up to 400 atm. on the cell $\text{H}_2 | \text{HCl}(0.1N), \text{HgCl}-\text{Hg}$ at 25° , and found for the change of e.m.f. $dE = 0.02958 \log p + 6.56 \times 10^{-6}(p-1) + 3.7 \times 10^{-10}(p^2-1)$. R. H. Gerke studied the e.m.f. of the cell $\text{Hg} | \text{HgCl}, N\text{-HCl} | \text{Cl}_2$ at atm. press. B. H. Buttle and J. T. Hewitt give the **ionization constant** $\text{HgCl} = \text{Hg}^{++} + \text{Cl}^-$ as 5.3×10^{-8} .

Mercurous chloride has no smell and no taste. Calomel is not altered when exposed to air in darkness, but in *light*, according to G. Suckow,¹² calomel acquires superficially a grey tint. R. Abegg found that it is also coloured by exposure to the cathode rays. L. Gmelin suggested that the grey product is *mercurous subchloride*, Hg_4Cl_2 ; but the action is probably a decomposition of the calomel into mercuric chloride and mercury, $2\text{HgCl} = \text{Hg} + \text{HgCl}_2$. Thus, J. von Tugolessoff says:

Sheets of paper were soaked in a soln. of mercurous nitrate, dipped in a dil. soln. of hydrochloric acid, dried, and exposed under a negative plate to light. The action of the light was to be detected by means of the mercuramide compounds. Since those of the mercurous salt are black and those of the mercuric salt are white, it was expected that ammonia would only blacken the parts which had not been exposed to light. The experiment did not turn out at first as had been hoped, for the whole sheet of paper was blackened by ammonia. After a short treatment with very dil. hydrochloric acid, the high lights became white. This shows that mercurous chloride is unquestionably changed to mercuric salt by light, but not completely; and consequently the test was spoiled by the ammonia reacting with some of the undecomposed mercurous salt. Since the amount of this latter was not large, a very short exposure to acid was sufficient to remove it, while the acid had practically no more effect on the portions which had not been exposed to light.

Calomel is blackened when exposed to light while confined under water, and A. Vogel

could find no sign of the evolution of any gas during the change. According to A. Mailfert, *ozone* acts slowly on mercurous chloride, forming mercuric chloride and a brick-red precipitate, apparently an oxychloride.

Mercurous chloride is very sparingly soluble in water. According to F. Kohlrausch,¹³ a litre of water dissolves 0.002 grm. of mercurous chloride at 18° or 0.0014 grm. at 0.5°; 0.0021 grm. at 18°; 0.0028 grm. at 24.6°; and 0.0070 grm. at 43°. Several other data have been calculated from the electrical conductivity or from the electromotive force of galvanic cells by H. Ley and C. Heimbucher, A. Ogg, R. Behrend, L. Rolla, M. S. Sherrill, M. de K. Thompson, etc. L. Sauer found that the finely divided salt is 10 per cent. more soluble than coarse-grained.

There have been many discrepant statements as to the conversion of mercurous into mercuric chloride by water, the chlorides of the alkali metals, and by organic acids. P. Hoglan¹⁴ found that calomel is slowly converted into corrosive sublimate by water at the temp. of the body and that the presence of sodium chloride, citric acid, or sugar favours the conversion. Some discrepant statements are due to a comparison of results obtained at different temp., at low temp. the conversion is slow, while at body temp. calomel is an unstable compound. M. Berthé says the conversion of mercurous to mercuric chloride by water or alcohol occurs at least at 40° or 50°. S. Hada found when freshly precipitated mercurous chloride is heated with water for 7 hrs. in a flask immersed in boiling water, mercury collects as a sublimate and mercuric chloride is found in the soln. The results with a current of air and a current of carbon dioxide were virtually the same; about one-tenth of a gram of mercury was present as mercuric chloride per gram of mercurous chloride employed, the amount of mercuric chloride was augmented to 0.13 grm. by the presence of hydrochloric acid, and nearly doubled by the presence of alkali chloride. According to G. Righini, steam partially converts calomel into a grey product with an excess of mercury and mercuric chloride; similar remarks apply to the action of boiling water. According to M. Donovan, N. J. B. G. Guibourt, W. Gruner, and A. Vogel, the grey product is a basic mercurous chloride, because (i) it recovers its whiteness when boiled with hydrochloric acid; (ii) when sublimed it yields mercurous chloride and mercury; and (iii) the water contains a little hydrochloric acid, and mercuric chloride. S. Hada found that if shaded from light, there is no sign of the grey product or of any oxidation of the mercury by hydrolytic dissociation, for mercurous chloride may be boiled indefinitely with water without suffering any change in appearance or composition. Indeed, according to W. Gruner and J. F. Simon, the calomel "almost wholly disappears after six boilings," when with water frequently replaced, and the water contains mercuric chloride; and, according to L. Mailhe, and S. Hada, the conversion of mercurous into mercuric chloride is faster if air has access to the liquid. In his study: *How mercurous and mercuric salts change into each other*, S. Hada could find no evidence of any oxidation during the decomposition of mercurous into mercuric chloride under these conditions, and he says dissociation fully accounts for all the facts observed. He finds that calomel is scarcely altered when heated for 6 hrs. to 150° with water in a sealed tube in an atm. of carbon dioxide—dissociation is hindered by the retention of the mercury vapour; although more dissociation occurs if hydrochloric acid or potassium chloride be present than with water alone. If the atm. in the tube contains oxygen, the mercury is oxidized—part of the oxychloride remains in soln. and part separates as brown glistening micaceous scales.

Two **mercurous oxychlorides** occur in small quantities in nature as secondary minerals, derivatives of cinnabar; the one, *eglestonite*, $\text{Hg}_2\text{O} \cdot 2\text{HgCl}$, occurs in brown crystals belonging to the cubic system along with mercury and mercuric sulphide at Terlingua (Texas).¹⁵ The sp. gr. is 8.327; hardness, 2 to 3. A. J. Moses' and B. F. Hill's analyses gave $\text{Hg}_6\text{O}_9\text{Cl}_3$, but W. F. Hillebrand and W. T. Schaller's is that generally accepted— Hg_4OCl_2 . The other mercurous oxychloride is *terlinguaite*, which occurs at Terlingua (Texas) in sulphur-yellow needles or plates belonging to the monoclinic system, with axial ratios $a : b : c = 1.6050 : 1 : 2.0245$,

and $\beta=105^{\circ} 37'$; sp. gr. 8.723 to 8.728; and hardness, 2 to 3. W. F. Hillebrand and W. T. Schaller's analyses agree with the formula $\text{HgO} \cdot \text{HgCl}$, so that it is a kind of mercuric mercurioxychloride. The colour gradually changes to an olive-green on exposure to sunlight. T. Fischer and H. von Wartenburg prepared artificial crystals of terlinguaite by heating a mixture of equi-mol. parts of mercuric oxide and mercurous chloride with water in a sealed tube at 180° .

According to H. Moissan,¹⁶ when mercurous chloride is warmed in the presence of *fluorine*, it furnishes a yellow surface skin of a compound insoluble in water; *chlorine* gas or chlorine water converts mercurous into mercuric chloride—according to M. Berthelot, $(\text{Hg}_2\text{Cl}_2, \text{Cl}_{2\text{aq}})=32.6$ to 45.6 Cals., and, according to J. Thomsen, 37.075 Cals. W. Eidmann and A. Naumann report that when chlorine is passed into acetone with mercurous chloride in suspension, only a small proportion of the latter is converted into the mercuric salt; *bromine* acts rapidly: $2\text{HgCl} + \text{Br}_2 = \text{HgCl}_2 + \text{HgBr}_2$; and with iodine: $2\text{HgCl} + \text{I}_2 = \text{HgCl}_2 + \text{HgI}_2$, and the sparingly soluble mercuric iodide is precipitated. A. Potilitzin found that bromine displaces some of the chlorine in mercurous chloride; M. C. Schuyten found that both bromine and iodine oxidize mercurous chloride; L. A. Planché and E. Soubeiran found that by triturating mercurous chloride with water and iodine both mercuric chloride and iodide are formed; and E. Riegel and F. Selmi prepared what he regarded as yellow crystals of **mercuric chloroiodide**, $2\text{HgCl}_2 \cdot \text{HgI}_2$, by heating mercurous chloride with iodine and much water until iodine vapour is no longer evolved—the yellow crystals which are deposited from the soln. become yellow in a few days. The mother liquid, according to F. Selmi, contains some mercurous chloride, chlorate, and iodate, and hydrochloric acid.

Mercurous chloride is very sparingly soluble in *hydrochloric acid*. E. Ruyssen and E. Varenne¹⁷ have measured the solubility of mercurous chloride in different amounts of hydrochloric acid, and they express the solubility as a ratio between the weight of mercurous chloride dissolved and the weight of acid—the solubility increases as the proportion of acid increases. At first the rate of dissolution is slow, but after several days, the rate of solution increases rapidly. Mercurous chloride is more soluble in the presence of silver chloride than when alone. The action of hydrogen sulphide on a hydrochloric acid soln. of mercurous chloride gives a precipitate ranging in colour from bright yellow to orange-yellow, according to the relative proportions of mercurous and mercuric chlorides in the soln. Expressing the results in grams of mercuric chloride per litre, T. W. Richards and E. H. Archibald found for the effect of hydrochloric acid on the solubility of mercurous chloride:

HCl	. 31.69	95.43	158.4	209.2	267.3	278.7	317.3	264.6
HgCl ₂	. 0.034	0.207	0.399	0.548	0.654	0.675	0.670	0.673
Sp. gr.	. —	0.042	1.069	1.091	1.114	1.119	1.132	1.153

N. J. B. G. Guibourt found that boiling water acidulated with hydrochloric acid dissolves mercurous chloride as mercuric chloride without the separation of mercury if air has access to the liquid, and L. Mailhe says that less is dissolved if the air be excluded. Thus, between 40° and 50° , 100 parts of calomel in a stoppered bottle with 100 parts of hydrochloric acid and 1667 parts of water, thoroughly freed from air by boiling, take up 0.67 part of mercuric chloride in 24 hrs., while in an open vessel, 2.32 parts were taken up. L. J. Proust, and P. F. G. Boullay say that boiling hydrochloric acid decomposes mercurous chloride, forming mercuric chloride and mercury; and, according to M. Berthelot, **mercuric hydrochloride**, $\text{HgCl}_2 \cdot n\text{HCl}$, is the product of the action. M. Pettenkofer, C. H. Pfaff, and H. Hennell found that when a mixture of ammonium chloride and calomel is sublimed, the sublimate is a double ammonium mercuric chloride, and a similar action is supposed to occur when calomel is boiled with an aq. soln. of ammonium chloride. In subliming a mixture of sodium and mercurous chloride, the latter is not decomposed. Like hydrochloric acid, aq. soln. of the chlorides of sodium, barium, calcium, etc.,

in contact with mercurous chloride form mercury and mercuric chloride. L. Mailhe, A. Larocque, J. Gewecke, and J. F. Simon reported that soln. of ammonium chloride take up mercuric chloride from mercurous chloride at ordinary temp., the action being faster between 40° and 50°; and faster with conc. than with dil. soln.; and faster in the presence of air than in its absence. On the other hand, T. Martius, and P. H. le Page say that dil. soln. of ammonium chloride have no such action. Alkali and other metal chlorides behave like ammonium chloride, but the action is less pronounced. The reaction seems to have been noticed by J. Capellina in 1576 before L. J. Proust's study in 1815; H. Pick said that mercurous chloride is blackened by a soln. of potassium chloride. *Au contraire*, A. Larocque said that soln. of the alkali chlorides dissolve the calomel as calomel without changing it simultaneously to mercuric chloride, because when the soln. is agitated with ether no mercuric chloride is extracted by this solvent. The action takes place in darkness. T. W. Richards and E. H. Archibald say the action is more marked with sodium chloride than with barium chloride, and with barium chloride more than with calcium chloride; while the action is scarcely perceptible with cadmium chloride. The quantity of mercuric chloride formed increases with increasing conc., and with hydrochloric acid, the maximum is attained when the conc. of the acid is 7*N*-HCl. According to H. Hennell, the decomposition of the calomel is complete after boiling it 10 times with a soln. containing an equal weight of sodium chloride. A. Ditte said that it must be admitted that calomel is feebly dissociated by cold water, but much more by hot water; in the presence of an alkali halide a double salt is formed which disturbs the equilibrium of dissociation, and more calomel is dissociated, and this continues until the double salt is also in equilibrium with its components. The potential of the normal calomel electrode is determined by the formation of a little mercuric chloride when a conc. soln. of sodium chloride acts on calomel. According to T. W. Richards and E. H. Archibald, the action of the dissolved mercuric chloride on the decomposition of the calomel is not catalytic; it is conditioned by a state of equilibrium which is a simple function of the square of the conc. of the chloride ions in not too conc. a soln. The general results point to the existence of an ionized complex HgCl_4^{--} in the soln. A. Gockel, and T. W. Richards have measured the temp. coeff. $-d\pi/dT$ of the potential, π , of cells ($-d\pi/dT = \pi/T - Q/\epsilon_0 T$, where Q denotes the change in the total energy—the heat of the reaction—and ϵ_0 is Faraday's constant) with calomel electrodes and soln. of different chlorides: $\text{Hg} | \text{HgCl}, \text{MCl}_n, \text{HgCl} | \text{Hg}$. T. W. Richards gives, between 0° and 30°:

	Normal.	γ_0 -normal.	γ_{10} -normal.
Hydrochloric acid	0.00033	0.00055	0.00066
Lithium chloride	0.00063	0.00083	0.00100
Sodium chloride	0.00056	0.00078	0.00095
Potassium chloride. . . .	0.00061	0.00079	0.00094
Calcium chloride	0.00053	0.00076	—
Strontium chloride. . . .	0.00053	0.00074	0.00092
Barium chloride	0.00053	0.00073	0.00092
Magnesium chloride	—	0.00076	0.00096
Zinc chloride. . . .	0.00063	0.00078	0.00095
Cadmium chloride	0.00069	0.00082	0.00097
Ammonium chloride	0.00058	0.00085	0.00120

The temp. coeff. increase with dilution, and decrease with rise of temp. Hydrochloric acid and ammonium chloride soln. occupy anomalous positions in the series owing to the presence of hydrogen ions in the former case, and the tendency to form amido-compounds in the latter case. The action of the different chlorides on mercurous chloride is of some importance because of the physiological action of calomel in therapeutics. It follows that in the presence of sodium chloride or hydrochloric acid some calomel will be transformed into corrosive sublimate; the amount of transformation will depend on the conc. of the soln. of alkali chloride rather than on the amount of calomel; and the action will be accelerated by blood corpuscles which act as carriers of oxygen. From this point of view the activity

of calomel is due to its conversion into soluble corrosive sublimate; E. Pollacci assumes that the activity of calomel is due to its being transformed into a very soluble mercuric thiocyanate by the alkali thiocyanates in the system. There is also to be considered the transformation of the calomel in pills and tabloids in the presence of sugar and other organic substances. F. Utz, for instance, says that there is a slow transformation of mercurous to mercuric chloride in tabloids made up with sugar, while R. Vive and T. Budde, and M. Soave say that there is no such change.

L. A. Planché and E. Soubeiran say that when triturated with **iodine water**, calomel forms soluble mercuric iodide and sparingly soluble mercuric iodide. According to F. Gramp, fuming **hydriodic acid** converts calomel into mercuric iodide, which is reduced to mercurous iodide if an excess of hydriodic acid be present. According to O. Wentzky, **alkali bromides** convert calomel quantitatively into mercurous bromide, and, according to K. Klingele, **alkali iodides** act similarly; while in conc. aq. soln. mercury and mercuric iodide separate out. F. Labouré says that aq. soln. of the iodides of magnesium zinc, and iron produce mercurous iodide and a soln. of the metal chloride.

When mercurous chloride is heated with **sulphur**, mercuric sulphide and chloride are formed, and, if the sulphur be in excess, mercuric sulphide and sulphur chloride, S_2Cl_2 . According to H. Feigl,¹⁸ a benzene soln. of **sulphur chloride** converts mercurous into mercuric chloride. A. Vogel found that a mixture of **antimony sulphide**, Sb_2S_5 , or Sb_2S_3 , and mercurous chloride gradually forms mercuric sulphide and antimony trichloride. The action is slow with the powdered materials in air, or under cold water; but under boiling water the action occupies but a few minutes. The same decomposition occurs under ether, turpentine, or oil of lavender, but not under alcohol. P. L. Geiger also studied the reaction, and says that the powders recently precipitated do not react if dried at 100° , but they do so if moist. W. Skey further adds that many other **metal sulphides** decompose calomel—e.g. auric sulphide forms gold and mercuric sulphide. A. Vogel stated that cold **sulphurous acid** colours mercurous chloride grey, the boiling acid black. He added that no mercury can be detected in the black precipitate, and he assumed that a **mercury subchloride** is formed, but E. Divers and T. Shimidzu say that no subchloride is formed, and that with purified materials the reaction is so slight that "we doubt whether there is any reaction at all between true mercurous chloride and sulphurous acid." J. A. Smythe and W. Wardlaw found that **sulphur dioxide** oxidizes mercurous to mercuric chloride: $SO_2 + 4HCl + 4HgCl = 4HgCl_2 + 2H_2O + S$; L. M. Stewart and W. Wardlaw found that there is a definite acidity at which the mercurous chloride is not changed, and with less than 0.016N-HCl, mercurous chloride is reduced incompletely to mercury. L. P. de St. Gilles says that **alkali sulphites** blacken mercurous chloride converting it into mercury, and a double salt of mercury and the alkali. C. Jones and W. Kirman say that some mercurous sulphite is formed; with a mol of sodium sulphite and one of mercurous chloride, half the mercury separates as metal, and half forms the double salt $Na_2Hg(SO_3)_2$, which is partially precipitated if a conc. soln. of sodium sulphite be employed. A. Vogel stated that **sulphuric acid** neither dissolves nor decomposes mercurous chloride, even after standing together for a long time; but that the hot acid dissolves the salt giving off sulphur dioxide but no hydrogen chloride, and leaves a residue of mercuric chloride and sulphate, the former of which partially sublimes. H. Rose noted that the vapour of **sulphur trioxide** is absorbed by mercurous chloride, forming a transparent mass. G. C. Wittstein found that mercurous chloride dissolves in a soln. of **ammonium sulphate**; while M. Pettenkofer found that a soln. of **potassium sulphate** has no action. A. Vogel noted that when boiled with **calcium sulphate**, mercurous chloride forms mercuric sulphate and calcium chloride, and he adds that **sodium sulphate** behaves in a similar manner. F. Faktor reported that a soln. of **sodium thiosulphate** dissolves mercurous chloride, and the soln. gives a black precipitate when warmed; and J. Schnauss, that mercurous chloride is partially reduced to metallic mercury

by sodium thiosulphate and partly dissolved to form a crystallizable double thio-sulphate.

H. Pick¹⁹ says that mercurous chloride is blackened by a soln. of **potassium nitrite**, when the proportion of the former is small and of the latter large—the blackening is due to the separation of mercury and a mercuric salt passes into soln. According to P. F. G. Boullay, and A. Vogel, cold **nitric acid** has no appreciable action on calomel, but the hot acid dissolves that salt, forming nitric oxide and a mixed soln. of mercuric chloride and nitrate: $6\text{HgCl} + 8\text{HNO}_3 = 3\text{HgCl}_2 + 3\text{Hg}(\text{NO}_3)_2 + 2\text{NO} + 4\text{H}_2\text{O}$. According to S. Schlesinger, this reaction occurs only with the conc. and warm acid. G. C. Wittstein says mercurous chloride is soluble in a soln. of **ammonium nitrate**; H. Debray, in hot soln. of **mercurous** and **mercuric nitrates**, and that it crystallizes from the former on cooling; H. W. F. Wackenroder, and E. Drechsel also noted the solubility of calomel in soln. of mercuric nitrate; and M. Pettenkofer says that a soln. of **potassium nitrate** has no action.

G. Gore, and E. C. Franklin and C. A. Kraus found that mercurous chloride is soluble in **liquid ammonia**; and R. J. Kane noted the blackening produced when aqua ammonia acts on the salt, and he believed the product is *dimercurous ammonium chloride*, $\text{Hg}_2\text{Cl}(\text{NH}_2)$, while H. Rose, and F. Isambert believed it to be an addition product, mercurous ammino-chloride, $\text{HgCl}.\text{NH}_3$. With ordinarily dried materials the action is slow; it is probable, said J. Sen, that thoroughly dried ammonia and mercurous chloride will have no action on one another, although the black product was shown by C. Barfoed, and H. Saha and K. N. Choudhuri to be a mixture of mercuric chloroamide, $\text{Hg}(\text{NH}_2)\text{Cl}$, with metallic mercury: $2\text{HgCl} + 2\text{NH}_3 = \text{Hg} + \text{Hg}(\text{NH}_2)\text{Cl} + \text{NH}_4\text{Cl}$. This opinion that the so-called *black precipitate* is a mixture of metallic mercury with mercuric chloroamide is based on the observation of H. Saha and K. N. Choudhuri that the latter compound can be separated from the mercury in virtue of its solubility in conc. aqua ammonia, and on C. Barfoed's observations that (1) Nearly half the mercury which the precipitate contains disappears as vapour when the precipitate is freely exposed to air, the exposure being under conditions which render chemical decomposition most improbable; the precipitate at the same time loses its dark colour. (2) Exactly half the mercury exists in the precipitate uncombined, but does not all disappear as vapour, because a little of it acts on the rest of the precipitate, becoming fixed. (3) The white or pale compound left after the mercury has evaporated is the same as that precipitated by ammonia in a soln. of the corresponding mercuric salt—*viz.* $\text{Hg}(\text{NH}_2)\text{Cl}$. (4) The dark precipitates are, therefore, not mercurous ammonium compounds, as heretofore stated, but mixtures of mercuric chloroamide and mercury. J. G. F. Druce supposes the black precipitate to be a compound because when rubbed on copper, it does not amalgamate or perceptibly affect that metal, but later he formulated the reaction $2\text{NH}_4\text{OH} + \text{Hg}_2\text{Cl}_2 = \text{NH}_2\text{HgCl} + \text{NH}_4\text{Cl} + 2\text{H}_2\text{O} + \text{Hg}$. The mercurous ammino-chlorides have been studied by J. Sen, C. Barfoed, E. Cohen, etc. According to C. Barfoed, and H. Saha and K. N. Choudhuri, the black product obtained by H. Rose by exposing sublimed mercurous chloride to ammonia gas is not *mercurous ammino-chloride*, $\text{HgCl}.\text{NH}_3$, as was once supposed, but rather a mixture of free mercury with mercury amido-chloride, $\text{Hg}(\text{NH}_2)\text{Cl}$. F. Isambert measured the dissociation press. of the black product. K. A. Hofmann and E. C. Marburg made **mercurous hydrazine chloride**, $(\text{HgCl})_2\text{N}_2\text{H}_2$, by shaking a mixture of mercuric chloride with hydrazine sulphate or chloride in aq. soln. M. Adams says that an aq. soln. of *hydroxylamine hydrochloride* dissolves freshly precipitated mercurous chloride without forming a compound, and that a soln. of hydroxylamine in methyl alcohol gradually reduces mercurous chloride.

J. L. Gay Lussac and L. J. Thénard noted that when mercurous chloride is heated with phosphorus mercury is liberated without disengaging chlorine, and H. Davy found that the vapour of *phosphorus* converts mercurous chloride into mercury phosphide, and phosphorous chloride. According to A. Baudrimont, *phosphorus pentachloride* converts mercurous chloride into the mercuric salt, which then unites

with the excess of phosphorus pentachloride, forming a compound $3\text{HgCl}_2 \cdot 2\text{PCl}_5$; phosphorus trichloride is liberated during the reaction. When heated with one-third its weight of *arsenic*, F. Capitaine obtained a sublimate with yellow tetrahedral crystals of arsenic mercuri-chloride, AsHgCl , a compound which is decomposed by hot water, forming an amalgam with arsenic, arsenious oxide, and hydrogen chloride; it is also decomposed by heat into mercury, arsenic, and arsenic trichloride. According to Z. Klemensiewicz, mercurous chloride does not dissolve in molten *antimony trichloride*.

J. L. Gay Lussac and L. J. Thénard²⁰ reduced mercurous chloride to the metal by heating it with carbon, and W. A. Lampadius also decomposed the vapour of calomel by red-hot carbon. According to F. von Kügelgen, mercurous chloride reacts with about one-seventh its weight of *calcium carbide* when warmed to start the reaction; the whole mass then glows red hot, but the reaction is so slow that most of the mercury remains with the slag. C. W. Scheele found that an aq. soln. of *hydrocyanic acid* blackens mercurous chloride furnishing metallic mercury, mercuric cyanide, and hydrochloric acid, a reaction which L. Mailhe, and E. Riegel represented by the equation: $2\text{HgCl} + 2\text{HCy} = \text{Hg} + \text{HgCy}_2 + 2\text{HCl}$. E. Regimbeau says the black colour is a mixture with mercury as a kind of emulsion. The reaction is much more complex than this equation assumes. J. A. Buchner says a part of the mercurous chloride remains undecomposed, and L. Fouquet, that the acid which is produced brings the reaction to a standstill if it is not neutralized, for while hydrochloric acid is displaced by hydrocyanic acid in dil. soln., the reverse action occurs with conc. soln. D. Vitali says no mercuric chloride is formed; M. H. Deschamps says some ammonia or ammonium cyanide is produced; L. Mailhe says formic acid is produced; E. Soubeiran, and M. H. Deschamps say an organic compound is also formed; A. A. B. Bussy and H. Buignet, and E. Esteve say that some mercurous chloride is converted into mercury and mercuric chloride, and the latter passes into soln., but if sufficient hydrocyanic acid is used, the reaction is quantitative. E. Wollschläger believes the first action with dil. hydrocyanic acid can be represented: $2\text{HgCl} + \text{HCy} = \text{Hg} + \text{HgCyCl} + \text{HCl}$. M. Beranger, however, thinks the presence of mercuric chloride is doubtful. M. Cheynet emphasized that the association of preparations of hydrocyanic acid with calomel in medicines may give rise to chemical reactions in which mercuric cyanide is formed, but this is not more toxic than the hydrocyanic acid which it replaces; and G. Patein has shown that the toxicity of a dil. soln. of hydrocyanic acid—1.4 grms. per litre—is virtually the same as it is in contact with a great excess of calomel when the acid formed in the latter case has been neutralized. According to A. Ditte, calomel is decomposed by a conc. soln. of *potassium cyanide*, forming a potassium mercuric cyanide, potassium chloride, and mercury by an exothermal reaction. E. Pollacci said that *hydrothiocyanic acid*, HSCy , is present in the saliva, and reacts with calomel and forms mercuric thiocyanate.

Mercurous chloride gives up its chlorine to many of the base metals both in the dry and humid states. J. L. Gay Lussac and L. J. Thénard²¹ reduced calomel to the metal by heating it with *potassium* or *sodium*. When boiled with *copper* and water, A. Vogel noted that the soln. becomes green and the copper is covered with a black film from which hydrochloric acid extracts copper oxide leaving a residue of mercury, and H. Bonnewyn noted that a clean strip of copper is not changed in contact with calomel wetted with alcohol or ether, but if as little as $\frac{1}{50000}$ th of mercuric chloride be present the copper is blackened. According to K. Seubert and A. Schmidt, when calomel is heated with *magnesium* filings, mercury and some *magnesium amalgam* are formed; when the two suspended in water are boiled together the calomel is reduced to mercury; but in contact with *magnesium* and hydrochloric acid, calomel is but slowly attacked, and after a long time some mercury oxide is formed. H. Rose also says that calomel is reduced to mercury when boiled with many metals, but not with *zinc*. The heat of formation of mercurous chloride is greater than that of silver chloride, and the reduction of mercurous chloride by

silver is therefore an exothermal process, and J. N. Brönsted measured the potential π , and the temp. coeff. $d\pi/dT$ of the cell $\text{Ag} \mid \text{AgCl}, \text{KCl}_{\text{aq.}}, \text{HgCl} \mid \text{Hg}$, and hence calculated U , the heat effect of the reaction $\text{Ag} + \text{HgCl} = \text{Hg} + \text{AgCl}$ from Helmholtz's equation: $T(d\pi/dT) = \pi - U$, and found it to rise from 1300 cal. at 23° to 1550 cal. at 80° . F. Pollitzer's value is too low. A. Colson showed that the reaction between silver and mercurous chloride in a sealed vacuum tube between 150° and 300° is a reversible reaction limited by the press. of mercury vap.

According to R. J. Kane,²² when calomel is heated with dry *alkali hydroxides*, or the oxides or hydroxides of the alkaline earths, mercury, oxygen, and the alkali chloride are formed: $4\text{HgCl} + 4\text{KOH} = 4\text{KCl} + 2\text{H}_2\text{O} + \text{O}_2 + 4\text{Hg}$; and with aq. soln. of the alkali hydroxides black mercurous oxide is formed: $2\text{HgCl} + 2\text{KOH} = \text{Hg}_2\text{O} + \text{H}_2\text{O} + 2\text{KCl}$. J. A. Buchner noted that the filtrate still retains some mercurous salt, and I. Bhaduri added that the decomposition is incomplete, but progresses nearer completion by raising the temp.; and it can be completed by raising the temp. to the b.p., and repeating the operation with fresh alkali. C. Barfoed argued that the precipitate is a mixture of mercury with mercuric and mercurous oxides in varying proportions, and not of mercuric oxide and mercury; sometimes as much as 81 per cent. of mercurous oxide is present. The mercurous oxide is oxidized by air at ordinary temp. in light and in darkness. The precipitate gradually becomes paler owing to the volatilization (not oxidation) of the finely divided mercury. W. Herz measured values of $K = [\text{KOH}]^2/[\text{KCl}]^2$ and of $K_1 = [\text{KOH}]/[\text{KCl}]$ in the balanced reaction: $2\text{HgCl} + 2\text{KOH} = \text{Hg}_2\text{O} + 2\text{KCl} + \text{H}_2\text{O}$, and found at 25° for K_1 , numbers ranging from 0.0152 to 0.0166.

According to A. von Dieterich and L. Wöhler, if 0.001N-KOH to which phenolphthalein has been added, be shaken with mercurous chloride, the red colour disappears on account of neutralization, and the mixture becomes grey on account of the formation of mercurous hydroxide ($\text{HgCl} + \text{OH}' = \text{HgOH} + \text{Cl}'$). With 0.01N-KOH mercurous chloride becomes grey, but the red colour produced by phenolphthalein is not destroyed because the chlorine ions reach such a conc. that the above reaction is reversed. The addition of potassium chloride produces the same effect on the 0.001N-KOH. If a few drops of a sat. soln. of potassium chloride be added to the dilute potassium hydroxide soln. which has been shaken with mercurous chloride, the red colour is reproduced. A mixture of equal volumes of 0.01N-KOH and sat. potassium chloride soln. has no action on mercurous chloride, which remains perfectly white. If any of these soln., to which mercurous chloride has been added without causing the disappearance of the red colour of the phenolphthalein, be warmed, the red colour disappears and reappears on cooling.

H. Hager says that soln. of sodium hydrogen carbonate, NaHCO_3 , do not alter calomel, but if a trace of normal sodium carbonate, Na_2CO_3 , be present, the calomel becomes grey. The reaction with soln. of *sodium carbonate* is symbolized: $2\text{HgCl} + \text{Na}_2\text{CO}_3 = \text{Hg}_2\text{CO}_3 + 2\text{NaCl}$, and, according to G. Patein, the presence of sodium chloride accelerates the decomposition. W. Herz found at 25° for $K = [\text{Na}_2\text{CO}_3]/[\text{NaCl}]^2$, numbers ranging from 1.30 to 1.65. G. Vulpius has studied the transformation of mercurous into mercuric chloride when mixed with sugar and sodium hydrogen carbonate. G. C. Wittstein reported that soln. of *ammonium carbonate* colour mercurous chloride grey and quickly dissolve it, leaving a small residue of metallic mercury. According to J. A. Buchner, *magnesium carbonate* has no action on calomel in the presence of cold water, but when boiled, carbon dioxide is evolved, mercury separates out, and a soln. of magnesium mercuric chloride is formed; while, according to A. Vogel, when calomel is heated with water and magnesium or *calcium carbonate* the action is similar, and mercurous (or mercuric) oxide, calcium chloride, mercury, and carbon dioxide are formed; *barium and strontium carbonates* act similarly, but the action is more feeble.

A. Vogel found that a soln. of *stannous chloride* reduced calomel to the metal, slowly at ordinary temp., and rapidly when heated. F. Capitaine prepared dendritic crystals, *stannous tetrachloromercurite*, $\text{SnCl}_2 \cdot 2\text{HgCl}$, by heating 75 per cent. tin amalgam with mercurous chloride.

The mixture of the tin amalgam with six times its weight of mercurous chloride is

heated to about 250° in a large glass retort. When the frothing ceases, the retort is cooled and then broken. The grey spongy mass is separated from the mercury and pulverized. The powder is heated in a stoppered flask to a temp. not exceeding the b.p. of mercury. When the fumes of stannous chloride have ceased to come off, the desired salt sublimes, and stannic chloride and mercury remain behind. The flask is broken to cool the sublimate.

When the salt is heated part decomposes and part sublimes; when treated with water there is some decomposition and mercury separates. The *butyrum stanni* of the alchemists contained variable proportions of stannous and mercurous chlorides. W. von Gulewitsch prepared **aluminium benzene chloromercurite**, $\text{AlCl}_3 \cdot \text{HgCl} \cdot \text{C}_6\text{H}_6$, from a benzene soln. of the component salts. J. Schnauss²³ said that a mixed precipitate of silver and mercurous chlorides is not sensitive to light, and likewise the precipitate obtained by adding a soln. of mercurous chloride to one of silver nitrate, for it, too, always contains a little mercurous chloride. H. C. Jones obtained a white powder, which has been regarded as $\text{AgCl} \cdot 3\text{HgCl}$, by the action of silver amalgam on mercurous chloride. The yellow or red earthy mineral *bordosite* from Chili is regarded as a compound $\text{AgCl} \cdot 2\text{HgCl}$. H. C. Jones made a product considered to be **silver dichloromercurite**, $\text{HgCl} \cdot \text{AgCl}$, by triturating precipitated silver with a large excess of mercuric chloride, and after 3 or 4 weeks, heating the mixture in a long-necked flask for 12–20 hrs. on a water-bath. The product is separated from silver and mercurous chloride by levigation with water. The white product has a sp. gr. 6.495; it is blackened by ammonia. According to H. C. Jones, it is probable that NHAgHg_2Cl and NH_2AgHgCl are formed. According to N. Antoni and G. Turi, the blackening is due to the formation of metallic silver. Conc. hydrochloric acid extracts half the mercury.

C. Meineke said that mercurous chloride is oxidized to the mercuric salt by *ferric salts*, and also, but more slowly, by *potassium permanganate*. O. Aschan and G. Borenus²⁴ state that 95 per cent. *formic acid* dissolves 0.02 per cent. of mercurous chloride which has been dried at 100° —so that 100 c.c. of the soln. contain 0.018 gm. of HgCl —water alone dissolves but 0.0003 per cent. of HgCl , and calomel is reduced to the metal by a boiling soln. of *potassium formate*. According to G. Patein, *alkali acetates* act like the chlorides. J. Schoras found calomel to be incompletely reduced when heated with *oxalic acid*, but in sunlight, the reaction progresses to an end. H. Zilgien noted that when 3 drops of *lactic acid* and 25 c.c. of aqua ammonia are added to 0.05 gm. of calomel suspended in 10 c.c. of water, 0.008 gm. is converted into mercuric chloride—neither ammonia, lactic acid, nor ammonium lactate act in this way.

Calomel was formerly said to be insoluble in *alcohol* and *ether*; according to R. Vive and T. Budde,²⁵ calomel is partially decomposed by 90 per cent. alcohol; J. L. Lassaigne detected no mercuric chloride in the ether extract of calomel; and H. MacLagan says that alcohol, ether, and chloroform dissolve very small amounts of mercurous chloride which is at the same time decomposed. L. I. Shaw has measured the conductivity of soln. of calomel, in methyl alcohol, acetic anhydride, acetone, ethyl acetate, acetyl chloride, epichlorhydrin, dimethyl sulphate, benzonitrile, aniline, and salicylaldehyde.

F. B. Hofmann found that when calomel is shaken with water, and benzene, toluene, or chloroform, the powder is retained at the surface of contact of the two liquids owing to the partial wetting of the powder by both liquids. H. von Euler and G. Zimmerlund studied the adsorption of mercurous ions by mercury from soln. of mercurous chloride.

Calomel is insoluble in *acetone* and *benzonitrile* (A. Naumann, and L. I. Shaw said soluble); *ethyl acetate* (M. Hamers, and L. I. Shaw said soluble); *petrol ether*, *decane*, *hexane*, or *carbon disulphide* (W. von Gulewitsch); calomel is sparingly soluble in *nitromethane* at ordinary temp. (J. Kozak and G. Mariasz); in a soln. of *ammonium succinate* (G. C. Wittstein); in *chloroform*, *bromoform*, *ethyl bromide*, and *ethylene bromide* (O. Sule); calomel is soluble in *benzene* and other *aromatic hydrocarbons*, *amylene*, *caprylene*, and *turpentine* (W. von Gulewitsch); *pyridine* (A. Werner). According to S. J. Bendiner, a mixture of calomel and *iodoform* decomposes at ordinary temp. in light even when the

actinic rays are cut out, and when the mixture has stood for some time, according to O. Schweissinger, it is completely converted into a mixture of chloroform and mercuric iodide. H. Ost and A. Mente noted the formation of a crystalline compound with oxamide. According to E. Baroni and O. Borlinetto, calomel forms coloured compounds with the salts of quinine, but not with the alkaloid itself; it also reacts similarly with pilocarpine, cocaine, and heroiné. E. Pollacci says it is not reduced by formaldehyde, uric acid, hippuric acid, and glycose. H. D. Gibbs found calomel is blackened by liquid methylamine, and crystals are formed when the soln. is cooled with liquid ammonia.

Calomel is the *hydrargyri subchloridum* of the pharmacopœia; it is employed in making salves—with lard it forms the *ungentum hydrargyri subchloridi* of the pharmacopœia. If pure it is not toxic, but in presence of chlorides many regard it as a poison. Mixed with antimony sulphide guaiacum resin, and castor oil, it is the *pilula hydrargyri subchloridi composita* or Plummer's pill of the pharmacopœia used as a purgative.

§ 12. Mercuric Chloride

The history of mercuric chloride, HgCl_2 , or corrosive sublimate, has been discussed in the preceding section. L. Besnou¹ reported its occurrence in the Atacama desert (Iquique), and A. Frenzel in the volcanic district of one of the Molucca Islands; but there is room for doubt since the reports are based on a few qualitative trials.

The preparation of mercuric chloride.—(1) *By chlorinating mercury.*—As indicated in connection with mercurous chloride, mercuric chloride is formed by heating mercury in an excess of chlorine gas. C. Göpner² made it by shaking mercury with chlorine hydrate; and C. L. Berthollet, by passing a current of chlorine into a vessel containing mercury and water. A. Lottermoser prepared what he regarded as *colloidal mercuric chloride* by the action of chlorine water on a colloidal soln. of mercury until the liquid became colourless. E. Trutzer introduced chlorine under a small press. into a closed vessel containing mercury with or without water or other liquid medium, and kept continuously agitated so as to prevent the formation of a protective skin on the unattacked mercury. The temp. (say 20°) is kept below the volatilization point of mercury. The Saccharinfabrik patented a process for preparing mercuric chloride in which chlorine is passed through a quartz tube into boiling mercury contained in a quartz vessel. The mercuric chloride vapour is carried by a current of cold air into a condensing tower, where it collects in a voluminous mass of acicular crystals free from calomel. E. G. Moeys heated mercury, hydrogen chloride, and a silicate to the sublimation temp. The silicate acts as a stimulant and may be used over again. Mercuric chloride is also formed when mercury is dissolved in hot hydrochloric acid containing a little nitric acid, and the mixture warmed until the precipitated calomel is redissolved; the crystals obtained on evaporating the soln. are recrystallized from hot water. L. Mailhe detected the formation of mercuric chloride when an aq. soln. of ammonium, potassium, or sodium chloride is allowed to act on mercury in the presence of air. A. J. von Oettingen denied this reaction, but it was confirmed by K. Voit. The reaction was regarded as of great importance as offering a possible explanation

of the physiological action of mercury, and the insoluble mercurous compounds on animals and man.

The process described by the Latin-Geber in the thirteenth century was in use for a long time. Geber said :

Thoroughly mix a pound of mercury, two pounds of vitriol, a pound of calcined rock alum, a pound and a half of common salt, and a fourth part of saltpetre, and then sublime. Collect the white and dense product which collects on the upper parts of the vessel. . . . If the product of the first sublimation be turbid or unclean—which may be the result of your own negligence—it must be resublimed.

According to G. F. Hildebrandt, in the old Dutch process, three parts of mercury, two of sodium chloride, two of nitre, and four of calcined ferrous sulphate were triturated together, and then sublimed: $\text{Hg} + 2\text{NaCl} + 2\text{KNO}_3 + \text{Fe}_2\text{O}(\text{SO}_4)_2 = \text{Na}_2\text{SO}_4 + \text{K}_2\text{SO}_4 + \text{Fe}_2\text{O}_3 + \text{HgCl}_2 + 2\text{NO}_2$; the nitrous fumes were condensed in receivers containing water, and sold as *sublimate water* for the preparation of mercuric oxide—the nitre, added G. F. Hildebrandt, served no useful purpose. A. F. de Fourcroy (1792), and P. L. Geiger recommended similarly treating a mixture of 10 parts of mercury, 8 of sodium chloride, 6 of manganese dioxide, 11 of sulphuric acid, and 3 of water: $\text{Hg} + 2\text{NaCl} + \text{MnO}_2 + 2\text{H}_2\text{SO}_4 = \text{HgCl}_2 + \text{Na}_2\text{SO}_4 + \text{MnSO}_4 + 2\text{H}_2\text{O}$ —the yield, added P. L. Geiger, is 12·24 parts of corrosive sublimate. T. Fairley converted calomel into mercuric chloride by boiling it with an acidified soln. of an alkali hypochlorite. C. Schantz passed mercury through an atm. of chlorine into a bath of a liquid which does not readily absorb chlorine.

(2) *By chlorinating mercuric oxide*.—E. Pelouze projected mercuric oxide into a flask of chlorine; the formation of mercuric chloride was accompanied by the disengagement of heat and light. It is also formed when mercuric oxide is dissolved in hydrochloric acid; J. J. Berzelius, L. Mailhe, and J. Fonberg, obtained it by heating mercuric oxide with a soluble chloride, *e.g.*, mercuric chloride is formed when either mercurous or mercuric oxide is kept in contact with a soln. of sodium chloride between 40° and 50° for say 24 hrs. The liquid becomes alkaline owing to the formation of sodium hydroxide: $\text{HgO} + 2\text{NaCl} + \text{H}_2\text{O} = 2\text{NaOH} + \text{HgCl}_2$. J. J. Berzelius used a soln. of magnesium chloride and found some magnesium hydroxide was precipitated; R. Wagner recommended the mother liquors (magnesium chloride) from carnallite; C. Hochstetter used a soln. of calcium chloride, and calcium hydroxide was precipitated. L. H. F. Melsens, and J. Fonberg noted that if the chlorides of the alkaline earths are used, the excess can be removed by passing a current of carbon dioxide. H. Rose noted that mercuric oxide slowly precipitates manganese quantitatively as manganese oxide from soln. of manganous chloride; lead oxide from lead chloride; zinc oxychloride from zinc chloride; cupric oxide from cupric chloride; nickel oxide from nickel chloride; cobalt oxide from cobalt chloride; and a ferric oxychloride from ferric chloride. J. R. Spielmann, and P. F. Delkeskamp sublimed a mixture of mercuric oxide with ferrous sulphate and sodium chloride.

(3) *By the double decomposition between chlorine or the chloride or other mercuric salt*.—Mercuric chloride is formed during the double decomposition of mercuric salts by a metal chloride—*e.g.* A. G. Monnet made it by the action of an aq. soln. of sodium chloride on mercuric nitrate. The reaction between soln. of mercuric sulphate and sodium chloride is exothermal. E. Rupp and W. Klee add that the product obtained by treating mercuric sulphate with barium or calcium chloride is not satisfactory since basic salts are formed which contaminate the product. L. Mailhe also made mercuric chloride by the action of soln. of the metal chlorides on various mercurous salts—*e.g.* by a soln. of sodium chloride on mercurous chloride, bromide, iodide, nitrate, or tartrate. A boiling conc. soln. of mercurous nitrate is mixed with conc. hydrochloric acid so long as precipitation occurs; and the precipitate is boiled with as much hydrochloric acid as was used in its formation: $\text{HgNO}_3 + 2\text{HCl} = \text{HgCl}_2 + \text{H}_2\text{O} + \text{NO}_2$. The crystals of mercuric chloride separate on cooling, and they can be recrystallized from hot water.

J. von L. Kunckel, and G. F. Boulduc heated equal parts of mercurous sulphate and sodium chloride. This process is employed on a manufacturing scale. A little manganese dioxide—about one-tenth of the weight of mercurous sulphate employed—is preferably added to J. von L. Kunckel's mixture to prevent the formation of calomel from the mercurous sulphate which may be present. The manganese dioxide reacts with the sodium chloride, giving off chlorine which converts mercurous to mercuric chloride. H. Fleck says that if the sublimation be conducted in an atm. of hydrogen chloride, the product will be free from mercurous chloride.

The mixture is sublimed on a large scale in long-necked glass balloons which are placed on iron plates, surrounded up to their necks with sand and gently heated to drive off all the moisture. While the contents of the glass subliming pots are being dried, hoods leading into a flue are placed over the necks. The hoods are then replaced by small inverted conical condensers and sufficient sand is removed to uncover the upper half of the body of the flask. The heat is increased until the whole of the mercuric chloride has sublimed, and finally raised sufficient to make the crust of sublimate coherent, but not to melt it. When cold the glass balloons are broken and the cake of sublimate removed. A little less volatile calomel may collect on the lower part of the cake; this is removed and added to a subsequent sublimation. The operation is conducted in a good draught because of the very poisonous character of the fumes.

E. F. Anthon proposed to sublime a mixture of calomel with an excess of potassium bisulphate and sodium chloride. H. Boerhaave sublimed a mixture of mercuric nitrate, sodium chloride, and roasted ferrous sulphate.

W. Sievers saturated a soln. of mercuric nitrate of sp. gr. 1.197 with chlorine gas, and recrystallized the precipitated mercuric chloride many times from hot water. E. Chauvenet found that carbonyl chloride, COCl_2 , at 350° , converts mercuric sulphide, very rapidly into mercuric chloride. R. Wagner treated mercuric sulphate with hydrochloric acid, and after crystallizing out the mercuric chloride, he used the mother liquid to redissolve more mercury; or he treated mercuric sulphate with barium hydroxide, and extracted the mercuric oxide with hydrochloric acid.

Mercuric chloride can be tested for impurities in the following manner: A soln. of 5 grms. of mercuric chloride in 100 c.c. of water and 5 c.c. of hydrochloric acid of sp. gr. 1.124 is treated with hydrogen sulphide until all the mercury is precipitated; the clear filtrate, when evaporated to dryness on the water-bath, should not give a weighable residue. The precipitate can be agitated with 5 c.c. aqua ammonia, and 45 c.c. of water and filtered; if arsenic be absent, the filtrate will not give a yellow coloration when acidified with hydrochloric acid. If calomel be absent, a gram of the sample should dissolve completely in 25 c.c. of ether. O. Wolff noted that the orange fluorescence of some specimens of mercuric chloride is due to the contained mercurous chloride, and that the latter compound is always formed during the sublimation of mercuric chloride.

W. L. Hardin purified mercuric chloride by dissolving it in hot water, filtering, evaporating to crystallization, drying the crystals, and then subliming them from a porcelain vessel into a glass tube; and repeating the whole process once again. Some prefer to conduct the sublimation in a stream of dry chlorine so as to ensure the conversion of mercurous to mercuric chloride. K. Charitschkoff made **colloidal mercuric chloride** by the action of hydrogen chloride on a soln. of mercuric naphthenate in a hydrocarbon containing an excess of naphthenic acid.

The properties of mercuric chloride.—Commercial sublimate usually has the form of a translucent crystalline crust. W. J. Luczizky³ says that the sublimed **crystals** are bipyramids belonging to the rhombic system, and have axial ratios $a : b : c = 0.7251 : 1 : 1.0697$. E. Mitscherlich and H. J. Brooke also measured the crystal constants (Fig. 11); E. Mitscherlich and W. J. Luczizky obtained crystals with the habit illustrated in Fig. 12, by slowly cooling hot alcoholic or aq. soln. with a little zinc chloride in soln. The latter addition was also recommended by J. W. Retgers. H. Arctowsky obtained plate-like crystals by heating aq. soln. in a sealed tube to 130° – 200° ; and W. J. Luczizky obtained crystals with the habit

illustrated in Fig. 13, from soln. of mercuric chloride and bromide. According to W. J. Luczizky, and J. S. van Nest, it exists in two different rhombic forms of different stability, the normal stable form, and with mixtures of mercuric bromide. R. Marc

FIGS. 11 to 13.—Habits of Mercuric Chloride Crystals.

has studied the speed of crystallization from aq. soln.; and E. F. Farnau the crystalloluminescence of the mercury halides.

The reported values of the **specific gravity** vary from J. H. Hassenfratz's ⁴ 5.1398 to L. Playfair and J. P. Joule's 6.223. J. S. van Nest's value 5.45 ± 0.025 (20°) is fairly representative. N. Orloff gave the **molecular volume**, 50.97. C. Tourneux gave 5.43 for the sp. gr. at 15°/15°, 0.184 for the sp. vol., and 50 for the mol. vol. H. W. Foote and N. A. Martin gave 4.36 for the sp. gr. of the molten salt at 282°; and, according to E. B. R. Prideaux, the sp. gr. of the liquid falls from 4.398 at 281° to 4.238 at 357°, and for θ° between 280° and 335°, the sp. gr. $D = 4.400 - 0.002218(\theta - 280)$. 100 vols. of the elements at 860 mm. become 101.9 on combustion; at 760 mm., 101.8; and at 560 mm., 101.7; and the sp. gr. 4.380 of mercuric chloride at 560 mm. press. becomes 4.348 at 760 mm., and 4.336 at 860 mm. W. Biltz gave 49.8 for the mol. vol. A. Reis and L. Zimmermann gave 2.0 for the **hardness**.

The **melting point** given by J. S. van Nest ⁵ is 265°; by R. Kempf, 283°; 273° by J. C. G. de Marignac; by W. P. A. Jonker, and by T. Carnelley and W. C. Williams, 277°. The latter says that if the superincumbent press. is below a certain minimum value, called the critical press., it is impossible to melt mercuric chloride, ice, etc. The **boiling point** is 302.5°, according to F. M. G. Johnson; 302.5°, according to T. Carnelley; 296°, according to J. C. G. de Marignac; and 307°, according to F. Freyer and V. Meyer. The m.p. and b.p. are thus fairly close together, and at its m.p. mercuric chloride rapidly volatilizes. M. Faraday, H. Arctowsky and C. Zenghelis said that this salt volatilizes perceptibly at ordinary temp., while E. Riegel said that neither the solid salt nor the aq. soln. loses mercuric chloride by volatilization at ordinary temp. L. Vignon reported a loss of 4 per cent. during 60 hrs'. heating at 80°; O. Sule, 6.3 per cent. during 6 hrs'. at 101.5°; and H. Arctowsky found layers 2 mm. deep in similar dishes 2 cms. diameter lost in 20 hrs. 0.0011 gm. at 56.5°; 0.0089 gm. at 79°; and 0.28 gm. at 125°. R. Kempf noted the volatilization is much more rapid under reduced press. W. A. Hargreaves and W. T. Rowe took advantage of the low volatilizing temp. of mercuric chloride to estimate the amount employed with some explosives—gelignite, blasting gelatine, etc. The explosive is ground up with an equal weight of French chalk, and heated in a glass flask in a water oven while a current of air is aspirated through the flask and then into an absorption apparatus containing dil. sulphuric acid, which collects the mercuric chloride. O. Sule noticed that when an aq. soln. of mercuric chloride is evaporated some of the salt is volatilized with the steam, and this the more, according to A. Minozzi, the more conc. the soln.; but E. Esteve said that the conc. has little or no influence while the form of the vessel has a marked influence. M. Lehmann, F. Utz, and J. Volhard noted that the presence of sodium chloride prevents the volatilization of mercuric chloride from alcoholic soln. G. H. Bailey also noted that the volatilization of mercury chloride

occurs during the evaporation of ethereal as well as of aq. soln. L. Rotinjan and W. Suchodsky compute the **critical temperature** to be 703° , and H. Rassow found 703° . The value calculated from T. E. Thorpe and A. W. Rucker's formula $(T_b V_b - 273)/2(V_b - 1)$, where T_b denotes the absolute b.p., 577.4° K.; and V_b the sp. vol. at the b.p. C. M. Guldberg found the ratio T_b/T_c , where T_c denotes the absolute critical temp. is approximately equal to 0.67 for a number of corresponding liquids; for mercuric chloride, $T_b/T_c = 0.59$. M. Prud'homme, and E. van Aubel studied the relation between the critical temp., the b.p., and the m.p.

The **vapour pressure** has been measured by V. von Richter (200° – 279°), E. B. R. Prideaux (from 286.1° to 309.0°), and F. M. G. Johnson. The last-named gave for the vap. press. p in mm. of mercury at

p	152°	195°	231°	256°	262°	275°	278°	283°	302°
	3	20	82	198	237	375	421	481	754

When plotted, there is a distinct break in the slope of the vap. press. curve at the m.p., 277° . E. Wiedemann, K. Stelzner, and G. Niederschulte found the vap. press. at 60° to be 0.003 mm.; at 100° , 0.10 mm.; at 140° , 1.35 mm.; and numbers rather lower than those of F. M. G. Johnson for temp. up to 300° . From R. Clausius' formula $d \log p/dT = Q/RT^2$, assuming that the vapour is not dissociated, F. M. G. Johnson calculated the **latent heat of vaporization** between 760 mm. and 800 mm. to be 14.63 Cals.; E. B. R. Prideaux, 13.91 Cals.; the former gave for **Trouton's constant** 25.44, the latter 24.1. For a liquid boiling between 304° and 354° , the normal value is 22.19; and it is therefore inferred that the liquid is associated to some extent but not so greatly as with water and the alcohols for which $Q/T = 26$. W. Ramsay's constant, T_1/T_2 , is 1.040 (750 to 450 mm.). According to E. Beckmann, the **latent heat of fusion** is 16.9 cal. per gram.

The **vapour density**, according to E. Mitscherlich, is 9.8; and R. Rieth's values correspond with the **molecular weight**, 278.2; the calculated value for HgCl_2 is 271. A. Scott obtained a vap. density corresponding with a mol. wt. 155.6 at high temp. The mol. wt. calculated from the lowering of the f.p. of aq. soln., by E. Beckmann, and W. Biltz, is 266, and in alcoholic soln., 264. The mol. wt. calculated from the raising of the b.p. of aq. soln. by W. Landsberger, is 263, and of alcoholic soln. by W. Landsberger and A. W. C. Menzies, 269; of dil. ethereal soln. by R. Lespieau, approximates to that required for the undissociated mol., but in conc. soln. the value is greater; in acetone soln., P. Dutoit and L. Friderich found 271; and H. C. Jones, 269.5, and the value was not appreciably affected by dilution. In methyl acetate soln., H. Steiner found 248; in ethyl acetate soln., M. Hamers and A. Naumann found 262; in methyl sulphide soln., A. Werner, 251; in ethyl sulphide soln., A. Werner, 279; and in benzonitrile soln., A. Werner, 269; in urethane soln., N. Castoro, 271; in ethylurethane soln., L. Mascarelli and M. Ascoli, 256; in pyridine soln., J. Schröder, 287; and, added P. Walden and M. Centnerszwer, the mol. wt. in dil. soln. of pyridine is normal, in conc. soln. it is less than normal, and this the more the greater the conc. The b.p. of soln. of mercuric chloride in many organic solvents are in agreement with a non-associated mol. HgCl_2 , but in aq. soln. the data are so discordant among themselves that the conclusions are indefinite. The distribution ratio of mercuric chloride between benzene or toluene and water agrees with an associated mol. Hg_2Cl_4 or $\text{Hg} \cdot \text{HgCl}_4$ in aq. soln., a conclusion in agreement with observations on the f.p. of aq. soln.

H. V. Regnault's value for the **specific heat** of the solid from 13° to 98° is 0.0689; and J. N. Brönsted's value from 0° to 19° is 0.05019; the latter also gave 11.83 for the mol. ht. K. Jauch found the sp. ht. of soln. containing 0.5, 1.0, and 2.0 eq. of mercuric chloride per litre to be respectively 0.9834, 0.9675, and 0.9543 at 18° . According to A. Blümcke, the sp. ht. of aq. soln. containing 1.02, 2.07, and 3.03 per cent. of HgCl_2 are respectively 1.003, 0.983, and 0.961; and for 3.12, 9.87, and 17.26 per cent. alcoholic soln., respectively 0.667, 0.632, and 0.595. W. Timofejeff found the sp. ht. of soln. containing 25, 50, and 100 mols of methyl alcohol

per mol of HgCl_2 to be 0.50776, 0.55406, and 0.58236 respectively, and with ethyl alcohol, 0.52403, 0.55683, and 0.57865 respectively between 10° and 50° .

The **heat of formation**, according to J. Thomsen,⁶ is $(\text{Hg}, \text{Cl}_2)=63.16$ Cals.; W. Nernst gave 53.3 Cals.; and R. Varet gave 53.3 Cals. and later 49.8 Cals. J. Thomsen found for the **heat of solution** $(\text{HgCl}_2, \text{Aq.}, -3.3$ Cals., M. Berthelot, -3 Cals.; J. Thomsen also gave for the **heat of neutralization** $\text{HgO}+2\text{HCl}_{\text{aq.}}=18.92$ Cals.; $\text{HgO}+2\text{HCl}_{\text{gas}}=56.86$ Cals.; $2\text{HgCl}+\text{Cl}_2=43.77$ Cals.; and $\text{Hg}(\text{NO}_3)_{2\text{aq.}}+2\text{KCl}_{\text{aq.}}=12.93$ Cals. M. de K. Thompson gave -42.600 cals. for the **free energy** of formation of mercuric chloride; and M. S. Sherrill gave 19.13 Cals. for energy of formation from its ions.

The **index of refraction** of aq. soln. of mercuric chloride has been measured by C. Cheneveau,⁷ and by M. le Blanc and P. Rohland. The two latter found for 6.04 and 6.03 per cent. aq. soln. the respective indices of refraction 1.3382 and 1.3383; the respective **molecular refractions** by Gladstone and Dale's formula 19.25 and 19.42; and by Lorenz and Lorentz's formula 11.26 and 11.36. For 6.52 and 5.44 per cent. soln. in alcohol, the indices of refraction are 1.3666 and 1.3657; with the eq. refractions by Gladstone and Dale's formula 19.58, and 19.56, and by Lorenz and Lorentz's formula 11.24 and 11.23. Similarly, for 21.05 and 10.94 per cent. soln. in acetone, the respective indices of refraction 1.3793 and 1.3693; and Gladstone and Dale's formula 20.15 and 20.29, and by Lorenz and Lorentz's formula 11.55 and 11.65. O. Schönrock's values for the specific **electromagnetic rotatory power** for the plane of polarization, are:

	Water.	Alcohol.	Pyridine.	Amyl alcohol.	Acetone.
Per cent. HgCl_2 . . .	4.5256	23.5489	17.5312	10.9948	36.3488
Sp. gr.	1.03806	0.99885	1.15228	0.89550	1.15854
Rotatory power . . .	0.8599	0.8374	0.9665	0.8922	0.8290

B. O. Pierce studied the **emission spectra** of the three mercuric halides—chloride, bromide, and iodide, and found that the emission spectra of mercurous and mercuric chlorides have bands lying between the yellow and green mercury lines with a mid-point at about 5800. The continuous spectrum in the green region has many fine weak lines. He inferred that the emission spectra of the two heated mercury chlorides are the same, owing to the fact that mercurous chloride dissociates into mercuric chloride and chlorine, and that the continuous spectrum of each compound is due to mercuric chloride. A. C. Jones extended these results into the ultra-violet. E. J. Evans studied the **absorption spectrum** of mercuric chloride vapour. According to J. A. Wilkinson, mercuric chloride has a greenish **fluorescence**, and it shows a luminosity in ultra-violet light only if contaminated with mercurous chloride. A. L. Hughes has measured the **photoelectric effect** of mercuric chloride, and G. P. Dima found it to be smaller than for the corresponding bromide or iodide. According to W. Matthies,⁸ the **glow discharge** between platinum electrodes does not decompose the vapour of mercuric chloride, provided the current is not great enough to give the spectrum lines of mercury. Copper, iron, aluminium, and mercury electrodes cause decomposition without an electric current; a tantalum electrode is disintegrated. The glow discharge resembles that with the elementary gases generally; the potential gradient is higher than for nitrogen as are also the cathode and anode falls. According to P. D. Foote and F. L. Mohler, the **ionization potential** of mercuric chloride vapour is 12.1 volts.

S. Meyer found the **magnetic susceptibility** to be 0.17×10^{-6} unit of volume or -0.15 unit of mass. C. Fritsch measured the **electrical conductivity** of pressed plates of solid mercuric chloride. M. Faraday noted that while mercuric chloride did not conduct the voltaic current in the solid state, it did conduct when fluid, but, according to J. W. Clark and W. Hampe, the electrical conductivity of molten mercuric chloride is small, and a current can decompose the salt into mercurous chloride and chlorine. H. W. Foote and N. A. Martin found the sp. conductivity of the molten salt at 282° to be 2.5×10^{-4} and of the solid salt at 282° , 5.8×10^{-5} ; they also measured the sp. electrical conductivities of soln. of a mol of caesium,

potassium, ammonium, sodium, and cuprous chlorides in v litres of the molten mercuric chloride at 282° ,:

	CsCl		KCl		NH ₄ Cl		NaCl		CuCl	
v	5	30	2	30	4	15	2	15	2	20
Conductivity	70.0	44.0	81.0	38.5	70.0	46.5	51.5	28.0	70.0	24.0

H. W. Foote and N. A. Martin consider that complex ions—possibly MHgCl_4' and NHgCl_5'' —are formed in these soln. The chlorides of the bivalent metals are but sparingly soluble in mercuric chloride. G. Schulze found that, unlike the majority of electrolytes, mercuric chloride at 300° has no influence on the potential of the electrolytic valve-action of tantalum.

Cold sat. soln. of mercuric chloride were found by W. Hampe,⁹ M. Faraday, and H. Morse to be poor conductors of electricity. The conductivity of aq. soln. has been measured by O. Grottrian, T. C. Fitzpatrick, H. Ley and H. Kissel, H. C. Jones and K. Ota, L. Kahlenberg, and K. Holdermann. H. Ley found at 25° , with platinized electrodes, for a gram-eq. of the salt in v litres of water:

v	16	32	64	128	256
λ	1.09	1.66	2.55	3.99	6.32

The conductivities are rather less with plain than with platinized-platinum electrodes. H. Arctowsky found that the electrical conductivity of aq. soln. increases perceptibly on standing—presumably because of hydrolysis, and the corresponding formation of hydrochloric acid. E. Rimbach and O. Weber find the conductivity is depressed when lævulose is present in the soln. S. Arrhenius, T. C. Fitzpatrick, L. I. Shaw, W. Hampe, and C. Cattaneo studied soln. of mercuric chloride in ether; L. Kahlenberg and A. T. Lincoln, H. C. Jones, L. I. Shaw and S. von Laszczynsky, in acetone; H. Steiner, in methyl acetate; J. W. Walker and F. M. G. Johnson, in acetamide; H. D. Gibbs, in methylamine; J. Kozak and G. Mariasz, in nitromethane; L. I. Shaw, in epichlorhydrin, acetylchloride, ethyl acetate, benzonitrile, acetic anhydride, salicyl aldehyde, and in aniline. L. I. Shaw failed to confirm the parallelism between the ionizing power and the dielectric constant of these solvents. H. Morse, and W. Hittorf made experiments on the **transport numbers**; and G. von Elissaffoff, on the **electrical endomose** of aq. soln.

D. Carnegie and F. Burt,¹⁰ and W. Biltz have commented upon the very small **degree of ionization** in aq. soln. of mercuric chloride as revealed by the conductivities, f.p., and b.p. of aq. soln. R. Luther, K. Drucker, M. S. Sherrill calculated the ionization constant K for $\text{Hg}'' + 2\text{Cl}' = \text{HgCl}_2$ is $[\text{Hg}''][\text{Cl}']^2 = K[\text{HgCl}_2]$, from the e.m.f. of the cell $\text{Hg} | \text{HgCl}_2, \text{Hg}(\text{NO}_3)_2 | \text{Hg}$, and from the solubility of silver chloride in mercuric nitrate, and the partition of mercuric chloride between toluene and water, and between toluene and mercuric nitrate soln. They find that K is between 1.0×10^{-14} and 1.5×10^{-14} . The existence of the ions HgCl' was established by H. N. Morse from the transport numbers, so that the ionization of mercuric chloride $\text{HgCl}_2 = \text{Hg}'' + 2\text{Cl}'$ takes place in stages, $\text{HgCl}_2 = \text{HgCl}' + \text{Cl}'$, and $\text{HgCl}' = \text{Hg}'' + \text{Cl}'$. The ionization constants for the two last-named processes are $[\text{HgCl}'][\text{Cl}'] = K_1[\text{HgCl}_2]$, where $K_1 = 2.8 \times 10^{-7}$; and $[\text{Hg}''][\text{Cl}'] = K_2[\text{HgCl}']$, where $K_2 = 3.5 \times 10^{-8}$. According to R. Luther, a soln. of mercuric chloride sat. at 25° contains the following constituents, expressed in mols per litre: $[\text{HgCl}_2] = 0.26$; $[\text{HgCl}'] = 0.00015$; $[\text{H}'] = 0.00033$; $[\text{Cl}'] = 0.00048$; $[\text{Hg}'] = 10^{-8}$; $[\text{HgCl}_4''] = 5 \times 10^{-6}$. M. S. Sherrill gives analogous data, and adds that sat. soln. of the mercurous halides have more Hg_2'' -ions than the corresponding mercuric halides have Hg'' -ions. The equilibrium constants are $[\text{HgCl}_4''] = 9 \times 10^{15}[\text{Hg}''][\text{Cl}']^4$; and $[\text{HgCl}_4''] = 90[\text{HgCl}_2][\text{Cl}']^2$. According to S. Arrhenius, the degree of ionization of a $\frac{1}{8}\text{N}$ -soln. of mercuric chloride when treated with one per cent. by vol. of methyl or ethyl alcohol is changed respectively 0.010 or 0.0112 per cent. R. Salvadori says the salt is more ionized in boiling methyl alcohol than in water or ethyl alcohol. According to F. Röhrs, soln. with a mol of the salt in 6 and in 48 litres of alcohol are ionized respectively 4 and 15 per cent. J. Timmermans has investigated the degree of ionization of soln. in alcohols, aldehydes, ketones, and nitriles.

The older determinations of the **solubility** of mercuric chloride in water were made by G. J. Mulder,¹¹ J. R. Spielmann, T. Bergmann, A. F. de Fourcroy, J. Davy, and by C. F. Wenzel. More recent determinations have been made by A. B. Poggiale, F. Jander, M. S. Sherrill, H. N. Morse, J. B. Hannay, H. W. Foote and L. H. Levy, A. Étard, and P. Rohland. The data, expressed in grams of salt per 100 grms. of soln., show:

	0°	10°	20°	30°	40°	60°	80°	100°	120°	150°
Per cent. HgCl_2	3.5	4.5	5.4	7.2	9.3	14.0	23.1	38	59	78.5

F. Guthrie gives the eutectic or cryohydric temp. as -0.2° when 3.29 per cent. of mercuric chloride is present. From this temp. upwards, the solid phase is HgCl_2 . No hydrated salts are known, although D. Strömholm compared the solubilities of mercuric chloride in dry and aq. ether, and concluded that *monohydrated mercuric chloride*, $\text{HgCl}_2 \cdot \text{H}_2\text{O}$, is formed in ethereal soln., and exists in a state of equilibrium $\text{HgCl}_2 + \text{H}_2\text{O} \rightleftharpoons \text{HgCl}_2 \cdot \text{H}_2\text{O}$; he also concluded that still higher hydrates may be formed.

The **specific gravities** of soln. of mercuric chloride in various solvents have been measured by O. Grottrian and many others.¹² At 18.5° , C. Bischoff found that for aq. soln.:

Per cent. HgCl_2	1	2	3	4	5	6	6.32
Sp. gr.	1.0082	1.0166	1.0252	1.0339	1.0427	1.0512	1.0546

and J. Schröder found the sp. gr. of soln. of various conc. at 0° , 10° , 20° , and 30° . According to J. A. Groshans, at 20° , soln. of sp. gr. 1.0203 and 1.0403 have respectively 2.42 and 4.72 per cent. of mercuric chloride, and the vol. of the solute is 0.430 c.c. and 0.847 c.c. when the mol. vol. are 48.15 and 48.63 respectively. The sp. gr. of soln. in hydrochloric acid have been measured by M. le Blanc and P. Rohland, and R. Engel; in alcohol, by J. Schröder, F. Röhrs, and by W. Herz and F. Kuhn; in acetone, by M. le Blanc and F. Kuhn, and by E. Vogt; in methyl acetate, by F. Bezold, and by A. Naumann and F. Bezold; and in ethyl acetate, by E. Alexander. According to J. Wagner,¹³ the **viscosities** of *N*- and $\frac{1}{8}$ *N*- aq. soln. of mercuric chloride (water unity) are 1.0116 and 1.0042 respectively when the sp. gr. are 1.0275 and 1.0138. J. C. G. de Marignac has measured the velocity of **diffusion** of mercuric chloride in soln. of sodium chloride. F. M. Raoult, E. Beckmann and W. Biltz have found the lowerings of the f.p. of aq. soln. of 0.1867*N*- and 0.9230*N*- mercuric chloride to be 0.033 and 0.168 respectively, corresponding with a normal mol. wt. M. le Blanc and A. A. Noyes measured the effect of sodium or potassium chloride in soln. with the mercuric chloride on the f.p., and found evidence of the formation of complexes of the type KHgCl_3 —*vide infra*. S. Skinner, and W. Landsberger investigated the raising of the b.p. of aq. soln. of mercuric chloride. A. Benrath found that the presence of sodium or potassium chloride in soln. with the mercuric chloride gave results in harmony with the assumption that complex salts are formed. F. M. Raoult has measured the raising of the vap. press.

It has been known for a long time¹⁴ that aq. soln. of mercuric chloride redden litmus; this, says P. Rohland, is due to hydrolytic dissociation yielding an acid with free hydrogen ions which redden litmus, but do not effect methyl orange. From the electrical conductivities, C. Kullgren calculated that for a mol. of the salt in *v* litres of water, the **degree of hydrolytic dissociation** is:

<i>v</i>	8	32	128	512
Hydrolysis at 85.5°	0.60	1.35	2.99	6.91
Hydrolysis at 100°	0.45	1.06	2.31	4.87

The ratios of the two numbers 1.33 is nearly independent of the concentration of the soln. H. Ley suggested that the hydrolysis proceeds either $2\text{HgCl}_2 + \text{H}_2\text{O} = (\text{HgCl})_2\text{O} + 2\text{H}^+ + 2\text{Cl}^-$; or else $\text{HgCl}_2 + \text{H}_2\text{O} = \text{HgClOH} + \text{H}^+ + \text{Cl}^-$. L. Kahlenberg's results favour the first hypothesis. The hydrolysis is readily perceptible at 6° ; and its amount increases with rise of temp.; H. Arctowsky found that in a sealed tube at 80° the basic product $\text{HgCl}_2 \cdot 3\text{HgO}$ is formed, while at 150° a product

$\text{HgCl}_2 \cdot 4\text{HgO}$ of higher basicity is formed. From observations with the ultra-microscope at different temp. H. W. Fischer and E. Brieger say that in aq. soln. mercuric chloride is split into hydrochloric acid and a colloid, and that the addition of sodium chloride hinders the hydrolysis by forming Na_2HgCl_4 . K. Thümmel, therefore, regards the aq. soln. of mercuric chloride as containing an acid $\text{H}_2(\text{HgOCl}_2)$ because of the peculiar hydrolytic changes; the solubility of mercuric oxide in soln. of mercuric chloride to form mercuric oxychlorides he regards as evidence pointing in the same direction.

The solubility of mercuric chloride in a great number of solvents has been examined qualitatively or quantitatively. A. C. L. de Bruyn,¹⁵ P. Rohland, M. Centnerszwer, W. Timofejeff, and W. Herz and G. Anders have reported on its solubility in *methyl alcohol* or in mixtures of methyl alcohol and water. According to A. Étard, the percentage solubility in methyl alcohol is:

	-34°	-20°	-2°	4°	12°	36°	62°	100°	127°
Per cent. HgCl_2	7.6	11.5	18.7	23.2	27.6	53.1	63.6	68.7	75.2

There is a break in A. Étard's curve at 38°. W. Herz and F. Kuhn find evidence of the formation of an alcoholate, $\text{HgCl}_2 \cdot \text{CH}_3\text{OH}$. The percentage solubility in *ethyl alcohol* likewise found by A. Étard is:

	-60°	-55°	-30°	0°	10°	31°	62°	100°	138°
Per cent. HgCl_2	3.0	7.8	14.3	29.0	31.3	34.2	42.1	63.6	67.8

According to A. Étard, there are two breaks in this curve, one at -50° and one at 60°. The solubility is augmented by the presence of hydroxylamine hydrochloride. W. Herz and F. Kuhn have measured the solubility in mixtures of methyl and ethyl alcohols. P. Rohland, W. Timofejeff, and A. Étard have measured the solubilities in *propyl alcohol*. A. Étard finds that there is very little increase in the solubility up to 30°; at -32° he says the solubility is 14.7 per cent.; at 0°, 16.4 per cent.; at 41°, 18.2 per cent.; at 67°, 32.7 per cent.; at 100°, 43.8 per cent.; at 127°, 52.7 per cent. W. Herz and F. Kuhn measured the solubility in mixtures of methyl and propyl alcohols, and in ethyl and propyl alcohols. A. Étard gives for the percentage solubility in isobutyl alcohol, at -11°, 5.5 per cent.; at 0°, 6.7 per cent.; at 11°, 7.5 per cent.; at 63°, 19.3 per cent.; at 98°, 32.1 per cent.; and at 155°, 50.4 per cent. According to A. Étard, the solubility in isopropyl alcohol is almost the same as in isobutyl alcohol. A. Étard further gives the percentage solubilities in normal *butyl alcohol*, in *amyl alcohol*, and in *allyl alcohol*:

	n-Butyl alcohol			Amyl alcohol			Allyl alcohol		
	-21°	9°	82°	-13°	26°	106°	-21°	8°	22°
Per cent. HgCl_2	12.4	14.3	33.1	8.6	8.9	35.1	20.6	25.2	48.7

The solubility of mercuric chloride in *ether* has been noted by J. Davy, N. E. Henry, and H. P. Madsen. A. Étard found the solubility increases very little with variations of temperature, for it rises from 5.6 per cent. at -47° to 9.0 per cent. at 115°. D. Strömholm found the solubility of mercuric chloride in water is not much affected by the addition of ether; a sat. soln. of ether and mercuric chloride in water dissolves about 10 per cent. less salt than an aq. soln. without ether; on the other hand, the solubility of mercuric chloride in ether rises significantly when water is present. M. J. B. Orfila and J. L. Lassaigne noted that ether extracts mercuric chloride from its aq. soln. The partition of mercuric chloride between ether and water has been measured by A. Hantzsch and F. Sebalde, F. Mylius and C. Hüttner, D. Strömholm, and S. Skinner. D. Strömholm investigated the effect of additions of acetic acid, ethyl acetate, benzene, chloroform; and F. Mylius and C. Hüttner, the effect of hydrochloric acid on the ethereal soln.

Mercuric chloride dissolves in *acetone*, $\text{CO}(\text{CH}_3)_2$, forming a heavy colourless liquid. A. Étard measured the solubility over the temp. range -23° to 70°, and noticed that the solubility from 0° to 70° is virtually independent of temp., and A. H. W. Aten found the solubility decreases with rise of temp. above 10°; and, expressing the solubility in mols per cent., he found:

	-15°	0°	10°	10°	17°	25°
Mols of HgCl_2	14.5	14.3	18.7	23.5	23.2	22.8
Solid phase	$\text{HgCl}_2 \cdot (\text{CH}_3)_2\text{CO}$			HgCl_2		

F. Röhrs says that acetone is not a true solvent. The conc. soln., in darkness, changes from red to dark brown—possibly owing to the formation of the compound $\text{HgCl}_2 \cdot \text{CO}(\text{CH}_3)_2$; and E. Vogt says that in a few days, the colourless liquid becomes pale yellow without changing its general characteristics. W. Herz and M. Knoch studied the soln. of mercuric chloride in mixtures of acetone and water.

According to O. Aschan and G. Borenus, 95 per cent. *formic acid* dissolves at 19°, 2.1 per cent. of mercuric chloride and 100 c.c. of the soln. have 2.4226 grms. of HgCl_2 . A. Étard measured the solubility of mercuric chloride in *acetic acid* from which A. Benrath noted that the salt can be crystallized unchanged. According to A. Étard, the solubility rises from 2.7 per cent. at 21° to 8.0 per cent. at 61°, to 12 per cent. at 95°, to 16 per cent. at 115°, to 55 per cent. at 207°. The solubility curve in glacial acetic acid is almost a straight line. A. Étard also found the salt is very sparingly soluble in *propionic acid*, and in *butyric acid*; and that the solubilities of mercuric chloride in *methyl and ethyl formates and acetates* can be represented by almost straight lines. According to A. Étard, at -20°, -3°, 46°, *ethyl formate* dissolves respectively 29.6, 2.92, and 31.0 per cent. of mercuric chloride; at -20°, 24°, and 55°, *methyl acetate* dissolves respectively 42, 40.3, and 41.5 per cent. of mercuric chloride. The solubility in methyl acetate has also been studied by H. Steiner, J. Schröder, F. Bezold and A. Naumann. According to A. Étard, at -50°, 0°, and 19°, *ethyl acetate* dissolves respectively 39.6, 39.5, and 40.2 per cent. of this salt. The solubility in ethyl acetate has also been studied by E. Alexander, M. Hamers, A. Naumann, M. Dukelsky, and A. H. W. Aten. According to C. E. Linebarger, if sodium and mercuric chlorides be present in excess in soln. of ethyl acetate, the compound $\text{NaCl} \cdot 2\text{HgCl}_2$ is formed. M. Hamers, and W. Herz and G. Anders have studied the solubility in aq. soln. of ethyl acetate. According to A. Étard, at 22° and 48°, *amyl acetate* dissolves 18.3 and 18.5 per cent. of mercuric chloride; and at 20°, 55°, and 71°, *ethyl butyrate* dissolves respectively 12.6, 13.5, and 15.1 per cent. J. W. Klever said that mercuric chloride is soluble in *glycerol*; and W. Eidmann, sparingly soluble in *methylal*. G. Glock found that while mercuric chloride is insoluble in *oils and fats*, it can be obtained in soln. if it be first dissolved in water-free ketones, or in alcohol-free ether.

According to M. Dukelsky, mercuric chloride is insoluble in *carbon tetrachloride*; but O. Sule said that at room temp., this solvent dissolves 0.002 grm. M. Dukelsky measured the solubility of mercuric chloride in mixtures of carbon tetrachloride and methyl alcohol. According to M. Dukelsky, at 0° and 45.9°, *ethylene chloride* dissolves respectively 1.33 and 2.42 per cent. of mercuric chloride; and he has studied the solubility of this salt in mixtures of ethylene chloride and methyl alcohol. According to O. Sule, at room temp. *ethyl bromide* dissolves 2.01 per cent. of mercuric chloride; and *ethylene bromide*, 1.53 per cent. A. Werner said that mercuric chloride is soluble in *methyl sulphide*. M. Dukelsky said that its solubility in *chloroform* is very small, 0.01 and 0.12 per cent. respectively, at -20.5° and 44.2°; for the solubility at room temp., O. Sule gave 0.106 per cent. A. Hantzsch and F. Sebaltdt have studied the partition coeff. of mercuric chloride between water and chloroform; and M. Dukelsky, the solubility of mixtures of chloroform with methyl and ethyl alcohols, and ethyl acetate. At room temp. O. Sule found that *bromoform* dissolves 0.489 per cent. of mercuric chloride.

According to A. P. M. Franchimont, mercuric chloride is sparingly soluble in cold, but more soluble in hot *benzene*; M. S. Sherrill has also noted the solubility in benzene; and M. Dukelsky found that at 6.5°, 34.1°, and 69.0°, benzene dissolves respectively 0.26, 0.64, and 1.39 per cent. of mercuric chloride; according to W. Timofejeff, the solubility in mixtures of benzene and alcohol at 38°, is greater than that calculated from the solubilities in the two components; M. Dukelsky measured the solubility in mixtures of benzene with alcohol and with ethyl acetate. A. Hantzsch, F. Sebaltdt, and A. Vagt, and O. W. Brown measured the partition coeff. of mercuric chloride between *toluene* and water; and H. N. Morse between soln. of mercuric nitrate and toluene. A. Werner said that mercuric chloride is insoluble in *paratoluidine*, and very soluble in aq. *benzonitrile*, and other *aromatic nitriles*. A. Naumann and J. B. Kämmerer say benzonitrile copiously dissolves mercuric chloride with a feeble evolution of heat, forming a clear liquid. L. Mascarelli and M. Ascoli have studied the solubility in *o-nitrotoluidine*, *nitrobenzene*, *p-nitroanisol*, and in *α-nitronaphthalene*, and J. Schröder, and A. Naumann the solubility in *pyridine*. L. Kahlenberg said that mercuric chloride is soluble in *alkyl thiocyanates*. Z. Klemensiewicz found that mercuric chloride is soluble in molten *antimony trichloride*, and that the soln. for great dilutions conduct better than aq. soln.; for conc. soln. aq. soln. are the better conductors. E. H. Büchner said that mercuric chloride is insoluble in liquid *carbon dioxide*; and M. Centnerszwer, that it is insoluble in liquid *cyanogen*. E. Moles and M. Marquina found that the solubility of mercuric chloride is augmented by *glycerol and sucrose*, and depressed by *tartaric and citric acids*. The solubility in 100 parts of glycerol at 25° is 80. W. Herz and P. Schuftan measured the distribution of mercuric chloride between water and *tetralin*.

The chemical properties of mercuric chloride.—Mercuric chloride has a sharp metallic taste, and is very poisonous. The powdered salt is stable in *air*, and, according to J. Davy,¹⁶ is not decomposed in *sunlight*; indeed, M. Berthelot found

that the pure salt—dry or moist—is not decomposed in a sealed tube after exposure for a month to sunlight, although pharmaceutical preparations may decompose owing to the presence of reducing agents. O. Wolff could detect no signs of the decomposition of the salt confined in a tube transparent to ultra-violet rays, and exposed to sunlight for a month. In 1803 P. F. G. Boullay reported that the aq. soln. of mercuric chloride is decomposed in sunlight with the formation of mercurous chloride, and the liberation of oxygen and hydrochloric acid. J. Davy made a similar observation in 1822. V. Meyer kept soln. of mercuric chloride in spring water and in highly purified water for two months in darkness, and observed no sign of decomposition, although A. Verda said that the soln. slowly decomposes in darkness with the separation of mercuric oxide, while in light, mercurous chloride is formed. W. van Rijn found a soln. 1 : 5000 decomposed into mercurous chloride and mercuric oxychloride in a few days, and this was attributed to the effect of the cork or of traces of organic matter in the water, or of water on the glass vessel. L. Vignon made similar observations, and stated that the action of the ammonia and dust of the air, and of the products of the action of water on glass, lead to the decomposition of soln. of mercuric chloride exposed to the air. E. Burcker draws the general conclusion that if aq. soln. of mercuric chloride be protected from air and light, they do not change if the solvent be also free from organic and mineral impurities. K. Scheringa found that the effect with the glass of ordinary medicine bottles is only perceptible in a few cases. A. Michaelis says the 1 : 1000 soln. keeps very well in yellow glass bottles, but in blue or white ones it quickly changes. M. Delépine says that mercuric chloride soln. made from spring water with added sodium chloride will keep a week without perceptible change; and they can be kept longer if the soln. contains enough hydrochloric acid to decompose all the bicarbonates in soln. in the water.

H. Davy (1822) stated that the presence of hydrochloric acid or of ammonium chloride “hinders the decomposition by its affinity for mercuric chloride”; in the language of the ionic hypothesis the hydrolytic dissociation of mercuric chloride in aq. soln. is hindered by the presence of strongly ionized chlorides. V. Meyer, L. Vignon, E. Burcker, and A. Busch, made the analogous observations that hydrochloric acid, sodium chloride, tartaric acid, and generally, the chlorides or bromides of the alkalies or alkaline earths, hinder the decomposition of soln. of mercuric chloride. L. Vignon also says that the presence of sodium chloride hinders the decomposing action of sodium hydroxide or carbonate, but not very much that of ammonia; ammonium chloride acts in the reverse way, and both salts make the mercuric chloride soln. more stable in the presence of albumin. R. Bolling, and P. Rohland say that soln. in absolute alcohol are more stable than in water. A. Lesure observed no change after exposing aq. soln. of mercuric chloride to **ultra-violet light** for 15–30 mins. C. Doelter and H. Sirk noted that a one per cent. aq. soln. is coloured yellow after 30 days' exposure to the **radium radiations** from half a gram of radium chloride; and H. Becquerel found that these radiations reduced mercuric to mercurous chloride in the presence of oxalic acid just as occurs by exposure to light. M. Kofler has also studied the absorption of **radium emanations** by soln. of this salt.

C. D. Zenghelis¹⁷ found that **hydrogen** under ordinary conditions does not reduce a soln. of mercuric chloride, but it does so if the gas is allowed to bubble into the soln. through a filter-paper extraction thimble. H. Moissan noted that **fluorine** attacks mercuric chloride, slowly in the cold, rapidly when heated, forming a yellow fusible fluoride; and C. Poulenc that it volatilizes in **hydrogen fluoride** gas without decomposition, and it is not altered when fused in **ammonium fluoride**. When heated with **ammonium chloride**, it is not reduced, but a double salt sublimes in needle-like crystals. T. Fairley noted the reduction of mercuric to mercurous chloride by **hypochlorites**. A. Potilizin heated mercuric chloride and **bromine** in a sealed tube, and found 15.16 per cent. of chlorine was expelled. An aq. soln. of bromine, and an ethereal soln. of **iodine**, in light or in darkness, transform mercuric

chloride respectively into mercuric bromide and iodide. According to W. Herz and W. Paul, mercuric chloride soln. dissolve iodine, and this the more the greater the proportion of hydrogen chloride in soln. According to M. C. Schuyten, bromine and iodine displace the chlorine from moist mercuric chloride. F. Gramp found that mercuric chloride is in great part decomposed when heated 6 hrs. with iodine and water in a sealed tube at 250°. According to T. Harth, a soln. of two mols of potassium bromide and one of mercuric chloride gives a mixture of mercuric bromide and potassium chloride quantitatively; but a soln. of two mols of potassium chloride and one of mercuric bromide suffers no change. E. P. Perman said that if mercuric chloride be shaken with **potassium iodide** in the presence of a little moisture, mercuric iodide is formed; in aq. soln. mercuric iodide is precipitated and, according to P. Rohland, in acetone soln., potassium chloride is precipitated. This is a reversal of the behaviour of these salts in aq. soln., and corresponds with the fact that mercuric iodide is far more soluble in acetone than in water, and potassium chloride is less soluble. A series of potassium mercuric iodides are known. V. Borelli was unable to isolate a mixed *mercuric perchloratochloride*, Cl.Hg.ClO_4 , although he made the corresponding bromo-, chloro-, cyano-, and thiocyno-perchlorates. The presence of a mol of mercuric chloride per mol of perchlorate in soln. raises the electrical conductivity 0.028 per cent., but the addition of another 1.5 mols of the chloride causes no further increase in the conductivity.

A small proportion of **stannous chloride** precipitates mercurous chloride from soln. of mercuric chloride; a larger proportion precipitates mercury as a black powder; according to A. Vogel, some stannic oxide is formed at the same time. According to F. L. Winckler, stannous chloride likewise precipitates mercurous chloride from alcoholic soln. of the mercuric salt. According to J. Bostock, the reaction is so sensitive that one part of mercuric chloride in 500 parts of water is blackened by stannous chloride, and one part of the salt in 20,000 parts of water becomes grey, and gives a precipitate in 24 hrs.; according to P. L. Geiger, the grey colour is perceptible if but one part of mercuric chloride be present in 40,000 parts of water. Stannous chloride precipitates mercurous chloride from soln. in benzonitrile, methyl or ethyl acetate, methylal, and acetone; and from pyridine soln. mercury is precipitated. According to J. L. Proust, a soln. of **cuprous chloride** in hydrochloric acid precipitates mercurous chloride from soln. of mercuric chloride, but L. Gmelin says that the only precipitate so obtained is cuprous chloride. W. von Gulewitsch says a boiling soln. of **aluminium chloride** and mercuric chloride gives a precipitate of mercury and mercuric oxychloride; C. Winther found that when a mixed soln. of **ferrous chloride** and mercuric chloride is exposed to the ultra-violet light of a quartz lamp, mercurous and ferric chlorides are formed; the reaction is slowly reversed in darkness: $\text{HgCl}_2 + \text{FeCl}_2 \rightleftharpoons \text{FeCl}_3 + \text{HgCl}$, but rapidly if it be under conditions where an electric current can be obtained.

The cell was constructed as follows. In a glass funnel, closed at the lower end, a perforated platinum plate was fixed; the plate was soldered to a platinum wire which passed out through a hole in the funnel. On the plate a layer of platinized asbestos was placed and then the soln. which was exposed to the light from a quartz-mercury vapour lamp. After the illumination the differences of potential were measured, a platinum electrode being placed for this purpose in the upper liquid. The e.m.f. in some cases was as much as 0.1 volt, and currents of one milliamperé were obtained. Hence, the arrangement has been called a *light accumulator*.

According to H. Schulze,¹⁸ mercuric chloride is not changed when heated in **oxygen** free or nascent. W. D. Bancroft and H. B. Weiser did not get a mirror of mercury on a cold porcelain tube in a Bunsen's flame fed with mercuric chloride, but a white deposit is obtained which is a mixture of mercury and undecomposed salt, along with some black mercurous oxide. G. Tammann found that mercuric chloride accelerates the decomposition of hydrogen peroxide in neutral soln. According to A. Kolb, and M. Kohn, **hydrogen peroxide** reduces mercuric chloride in a neutral or acid soln. provided a neutral tartrate—sodium

potassium tartrate—be present and calomel is quantitatively formed; if heated in alkaline or ammoniacal soln., hydrogen peroxide or sodium peroxide reduces mercuric salts to the metal, a reaction utilized by M. Kohn and A. Ostersetzer for the quantitative determination of mercury in the mercuric halides. According to G. Bredig and W. Reinders, the reduction of mercuric chloride by hydrogen peroxide in neutral soln. is accelerated by colloidal gold or platinum. F. Olivari has shown that the solubility of sulphur or selenium in fused mercuric chloride is not reciprocal in that fused mercuric chloride dissolves **sulphur** or **selenium**, but is not dissolved by them. There is no reaction between mercuric chloride and these two elements at the fusion temp., but with **tellurium** and the fused salt, chemical action occurs to some extent and mercurous chloride is formed: $2\text{HgCl}_2 + \text{Te} \rightleftharpoons \text{Hg}_2\text{Cl}_2 + \text{TeCl}_2$. At presumably a higher temp., J. L. Proust found a reaction between mercuric chloride and sulphur, resulting in the formation of mercuric sulphide and sulphur chloride, and he adds that the decomposition may proceed explosively. According to J. Davy, mercuric chloride is not perceptibly attacked by sulphuric acid hot or cold; but, according to H. Rose, A. Vogel, and F. Mohr, when boiled with the acid, there is a very slight formation of mercuric sulphate and the greater part is volatilized unchanged. H. Rose said that mercuric chloride does not absorb the vapours of sulphuric anhydride, but, according to R. J. Kane, in the converse reaction, hydrogen chloride is absorbed with the evolution of heat by mercuric sulphate; and F. Mohr found the reaction: $\text{HgSO}_4 + 2\text{HCl} = \text{HgCl}_2 + \text{H}_2\text{SO}_4$, is completed at an elevated temp. H. Rose stated that a small proportion of **hydrogen sulphide** precipitates white mercuric sulphochloride, $2\text{HgS} \cdot \text{HgCl}_2$ or $\text{Hg}_3\text{S}_2\text{Cl}_2$, while an excess precipitates black mercuric sulphide. The **alkali-hydrosulphides** behave similarly. Dry hydrogen sulphide in ether, benzene, ethyl acetate, acetone, pyridine, or benzonitrile soln. of mercuric chloride at first gives a white precipitate which becomes yellow $2\text{HgS} \cdot \text{HgCl}_2$; in methyl acetate soln., mercuric sulphide is precipitated. Potassium sulphide has no action on soln. of mercuric chloride in benzonitrile; potassium or calcium sulphide likewise has no action with methylal soln. According to J. S. F. Pagenstecher, **metal sulphides**, like freshly precipitated sulphides of zinc, cadmium, lead, tin, copper, antimony, and iron when boiled with mercuric chloride form sulphides and precipitate mercuric sulphochloride: $\text{ZnS} + 2\text{HgCl}_2 = \text{ZnCl}_2 + \text{HgS} \cdot \text{HgCl}_2$; or $2\text{Sb}_2\text{S}_5 + 15\text{HgCl}_2 = 4\text{SbCl}_5 + 5\text{Hg}_3\text{S}_2\text{Cl}_2$. Native sulphides and metallic sulphides prepared in the dry way act slowly, or not at all—e.g. zinc blende or native antimony sulphide has no perceptible action. When mercuric chloride is heated in a sealed tube with a little water and lead sulphide, at 160° , A. Levallois observed the transformation: $\text{PbS} + \text{HgCl}_2 = \text{HgS} + \text{PbCl}_2$.

G. Viard found that an excess of **sulphuric acid** precipitates mercuric chloride from its aq. soln. In general, it may be said that mercuric chloride is fairly easily reduced to mercurous chloride. A. Vogel reported that **sulphurous acid** precipitates mercurous chloride and mercury from an aq. soln. of mercuric chloride; at ordinary temp. very little action is perceptible after 24 hrs., but when heated, the action is rapid. In order to precipitate all the mercury as mercurous chloride a large excess of sulphurous acid frequently renewed is necessary. A mixture of sulphurous acid and mercurous chloride gives no precipitate with an excess of alkalis. W. Sartorius showed that the conc. of the soln. determines the yield of mercurous chloride in the reduction of mercuric chloride by sulphur dioxide. A soln. of mercuric chloride (1 : 80) sat. with sulphur dioxide at 70° – 80° , gives a theoretical yield if kept a long time at that temp. A. Sander concluded that the reaction is $2\text{HgCl}_2 + \text{SO}_2 + 2\text{H}_2\text{O} = 2\text{HgCl} + 2\text{HCl} + \text{H}_2\text{SO}_4$, and is quantitative when the soln. does not contain over 2 grms. of sulphur dioxide per litre. With greater conc. the gas escapes unoxidized. L. M. Stewart and W. Wardlaw found quantitative reduction occurs when sulphur dioxide reacts at 95° with approximately 2.6 grms. of mercuric chloride in 120 c.c. of water. With a greater conc. of mercuric chloride, reduction is incomplete, and depends on the conc. of hydrochloric acid—*vide* mercurous chloride. According to E. Divers and T. Shimidzu, mercurous chloride is much more soluble in sulphurous

acid than in water; and the soln. on exposure to air rapidly crusts over and deposits a crystalline precipitate of mercuric chloride rendered less soluble by the escape of sulphur dioxide. The addition of sulphuric acid to the soln. of mercuric chloride in sulphurous acid lowers the solubility of the salt and mercuric chloride is precipitated. It is supposed that the soln. of mercuric chloride in sulphurous acid contains **mercuric hydrogen sulphite**: $\text{HgCl}_2 + 2\text{H}_2\text{SO}_3 \rightleftharpoons 2\text{HCl} + \text{Hg}(\text{HSO}_3)_2$. According to H. Debray, the presence of sodium chloride hinders the reducing action of sulphurous acid. A mercuric chloride soln. can be boiled without reduction if 20 times its weight of sodium chloride be present; but the reduction does occur even then if heated to 120° in sealed tubes. **Ammonium sulphite** has scarcely any action on mercuric chloride soln. in the cold, but if heated, plate-like crystals of mercurous chloride are quickly precipitated, and if the action be allowed to continue, the last-named salt is further reduced and blackened. P. Berthier separated the mercury in globules by warming the blackened mass with hydrochloric acid. According to L. P. de St. Gilles, cold **alkali sulphites** and mercuric chloride soln. form double salts. This accounts for E. Divers and T. Shimidzu's observation that mercuric chloride is much more soluble in a soln. of sodium sulphite or pyrosulphite than in water. N. N. Mittra and N. R. Dhar studied the induced reactions with mercuric chloride and sodium sulphate with sodium arsenite or arsenious acid. When a soln. of **sodium thiosulphate** is added to one of mercuric chloride, T. Poleck and C. Goercki say that no precipitate is at first formed, but the soln. becomes turbid in a few minutes, and later a white precipitate appears which turns yellow and then brown; the dark-coloured precipitate is probably a mixture of mercuric sulphochloride, sulphur, and free mercuric sulphide. According to E. T. Allen and J. L. Crenshaw, if the molar ratio $\text{HgCl}_2 : \text{Na}_2\text{S}_2\text{O}_3$ be greater than 3 : 2, white $2\text{HgS} \cdot \text{HgCl}_2$ is precipitated; if the ratio be 1 : 1 a mixture of this compound with black mercuric sulphide is formed; with a higher proportion of thiosulphate, say 1 : 4, black mercuric sulphide first separates out, a red precipitate of $\beta_1\text{-HgS}$ is formed, and the precipitate forms two layers—the upper red layer is $\beta_1\text{-HgS}$, and the lower one $\alpha_1\text{-HgS}$. C. R. Wise found that anhydrous **selenium oxychloride** dissolves 0.89 per cent. of mercuric chloride at 25° .

According to J. Davy,¹⁹ 100 parts of hot **nitric acid**, of sp. gr. 1.41, dissolve less than 0.2 part of mercuric chloride. S. Schlesinger says that if the boiling be protracted mercuric nitrate is formed, but this statement does not agree with J. Davy's, P. F. G. Boullay's, or with H. Rose's observations, where the dissolution takes place without decomposition. According to V. Thomas, mercuric chloride is not reduced by heating it with **nitrogen peroxide**, nor, according to J. J. Sudborough, is it changed by **nitrosyl chloride**. The action of **ammonia**, of **hydroxylamine**, and of **hydrazine** is discussed in three special sections—*vide infra*. N. R. Dhar studied the reduction of mercuric chloride with hydrazine hydrochloride and hydroxylamine hydrochloride in the presence of potassium permanganate. Dry ammonia gas in benzonitrile soln. of mercuric chloride gives a white precipitate of $\text{HgCl}_2 \cdot \text{NH}_3$; in pyridine, ethyl acetate, and methylal, a precipitate of $\text{HgCl}_2 \cdot 2\text{NH}_3$. According to G. von Knorre and K. Arndt, hydroxylamine is oxidized to nitrous and nitric oxides. H. Davy found that if the vapour of **phosphorus** be passed over heated mercuric chloride, mercury and phosphorous chloride are formed; while if phosphorus be heated with an aq. soln. of mercuric chloride, P. F. G. Boullay found mercury phosphide, phosphoric and hydrochloric acids were produced; and F. Fengler added that phosphorus precipitates mercurous chloride, but no mercury, from an ethereal soln. of mercuric chloride. H. Rose passed **hydrogen phosphide** over warm mercuric chloride, and observed a copious evolution of hydrogen chloride, and the formation of an orange-yellow sublimate of mercuric phosphide which was resolved into its constituents when heated further. H. Rose also found hydrogen phosphide precipitates yellow mercuric phosphochloride, $\text{Hg}_3\text{P}_2 \cdot 3\text{HgCl}_2 \cdot 3\text{H}_2\text{O}$, from aq. soln. of mercuric chloride; and P. Lemoult suggested this soln. as an absorbent for phosphine. A. Bergé and A. Reychler recommended mercuric chloride soln. for removing

phosphine from impure acetylene, but P. Biginelli showed that acetylides are formed by the action of acetylene on mercury chloride. B. Pelletier stated in 1792 that when **tin phosphide** is warmed with a soln. of mercuric chloride, hydrogen phosphide, mercury, and stannic chloride are formed. According to H. Rose, an excess of **hypophosphorous acid** precipitates metallic mercury from soln. of mercuric chloride, while if the mercuric salt be in excess, mercurous chloride is formed—J. R. Thompson obtained mercurous chloride, B. E. Howard the metal. According to H. Rose, **phosphorous acid** precipitates mercurous chloride completely from soln. of mercuric chloride. The reaction is accelerated by heat, and by the presence of nitric or hydrochloric acids. If the mercuric chloride be boiled with an excess of phosphorous acid, the mercurous chloride is grey, and mercury is obtained only in the presence of free acid. The dynamics of the reaction have been studied by C. Montemartini and U. Egidi, by J. B. Garner, J. E. Foglesong, and R. Wilson, and by G. A. Linhart. According to the latter, the reaction proceeds in two stages: $\text{HgCl}_2 + \text{H}_3\text{PO}_3 = \text{HCl} + \text{HgCl} + \text{H}_2\text{PO}_3$, followed by $2\text{H}_2\text{PO}_3 + \text{H}_2\text{O} = \text{H}_3\text{PO}_3 + \text{H}_3\text{PO}_4$. The last-named reduction is very fast in comparison with the speed of the former. N. N. Mittra and N. R. Dhar studied the induced reaction between mercuric chloride and sodium phosphite and sodium arsenite or arsenious acid. J. von Liebig noted that soln. of mercuric chloride give no turbidity when mixed with **alkali phosphates**, but after the mixture has stood a long time, a small red deposit appears, and it is rapidly formed with hot soln. K. Haack obtained mercuric oxychloride by the action of **disodium hydrophosphate** on mercuric chloride, and D. Carnegie and F. Burt obtained a dark red precipitate by mixing sat. soln. of **ammonium phosphate** and mercuric chloride. According to L. Amat, **hypophosphoric acid** with cold acid soln. of mercuric chloride furnished a quantitative yield of mercurous chloride. F. Capitaine and N. W. Fischer noted that when **arsenic** and mercuric chloride are heated together arsenic trichloride and a yellowish-brown sublimate of mercuric arsenio-chloride are formed. O. Borrichius found a mixture of **antimony** with one-third its weight of mercuric chloride when pressed into a glass tube becomes hot during the course of half an hour, and when heated forms antimony trichloride and mercury. A similar observation was made by F. Capitaine. N. W. Fischer said that antimony has no action on a soln. of mercuric chloride. **Hydrogen arsenide** was found by H. Rose, and J. Lohmann, to precipitate yellowish or reddish-brown Hg_3AsCl_5 . It is supposed that the reaction takes place in stages, first forming yellow chloromercurio arsine, $\text{AsH}_2\cdot\text{HgCl}$; orange dichloromercurio arsine, $\text{AsH}(\text{HgCl})_2$; brown trichloromercurio arsine, $\text{As}(\text{HgCl})_3$; and finally black arsenic mercuride, Hg_3As_2 . A. Partheil and E. Amort observed similar changes in alcoholic soln. of mercuric chloride chloromercurio arsine, $\text{AsH}_2\cdot\text{HgCl}$; dichloromercurio arsine, $\text{AsH}(\text{HgCl})_2$; and trichloromercurio arsine, $\text{As}(\text{HgCl})_3$; each forms arsenious acid, hydrochloric acid, and mercurous chloride in contact with an excess of the mercuric chloride soln. Arsenic mercuride under similar conditions forms mercurous chloride and arsenic, and it is easily decomposed by water, forming arsenious acid, hydrochloric acid, and mercury. G. Franceschi found that arsine precipitates $\text{HAs}(\text{HgCl})_2$ from an ethereal soln. of mercuric chloride. According to J. Lohmann, **hydrogen antimonide** at first gives no coloration with a mercuric chloride soln., the soln. then becomes turbid, and a white precipitate is formed; this becomes greyish-white, and consists of mercury and mercurous chloride and possibly some antimony and antimonious oxide. G. Franceschi also found an aq. or alcoholic soln. of mercuric chloride furnishes a precipitate of $\text{HSb}(\text{HgCl})_2\cdot 3\text{H}_2\text{O}$ when treated with hydrogen antimonide. H. Rose said that **arsenic oxide** is not altered by mercurous oxide, and K. Haack, that a **disodium hydroarsenate** precipitates mercuric arsenate and mercuric oxychloride. H. Bollenbach found **antimonious oxide** reduces mercuric to mercurous chloride; and F. Rosenthal and J. Severing, that **potassium hexatantalate** gives a precipitate with mercuric chloride.

According to F. W. O. von Coninck,²⁰ animal charcoal does not effect the decomposition of cold soln. of mercuric chloride. J. L. Gay Lussac and L. J. Thénard

reduced mercuric chloride to mercury by heating it with **carbon**, but, according to J. B. Nevins, mercuric chloride is not reduced by gentle ignition with dry charcoal even if hydrogen be passed over the mixture—the reduction occurs only if the charcoal be moistened; it is reduced if gently ignited with sugar, bread, and the like. The action of **acetylene** on mercuric chloride has been studied by M. Kutscheroff, H. Biltz and co-workers, K. A. Hofmann, P. Biginelli, J. S. S. Brame, B. C. Keiser, etc. A. Bergé and A. Reyckler said that acetylene has no action on a soln. of mercuric chloride in dil. hydrochloric acid, and recommended this liquid as a purifying agent for acetylene; but J. S. S. Brame, D. L. Chapman and W. J. Jenkins, and P. Biginelli have shown that the sat. soln. furnishes fine needle-shaped crystals of *chloromercurichloroacetylene*, ClHg.HC:CHCl , after standing some time—*vide* acetylides. G. Gore found that **carbon disulphide** immediately precipitates the sulphide from a soln. of mercuric chloride in ether. N. N. Mittra and N. R. Dhar studied the induced reaction between mercuric chloride and **formic acid** and sodium arsenite. M. Berthelot decomposed dil. soln. of mercuric chloride by **hydrocyanic acid**. H. Rose found **potassium cyanide** first makes the soln. turbid, and this afterwards clears when more cyanide is added, because mercuric chloride and cyanide form soluble complex compounds with mercuric cyanide and the alkali chloride. W. Feld heated mercuric chloride with **potassium ferrocyanide** and obtained mercuric cyanide and mercurous chloride; and H. Rose obtained a white precipitate with soln. of these two salts—the precipitate became blue on standing, and the liquid contained mercuric cyanide in soln. According to K. Schröder, a yellow precipitate of mercuric ferrocyanide is formed, with conc. soln. of potassium ferrocyanide and mercuric chloride. H. Grossmann obtained a crystalline potassium mercuric thiocyanate by mixing conc. soln. of mercuric chloride and **potassium thiocyanate**, but not with dil. soln. Potassium thiocyanate is without visible action on methylal soln. of mercuric chloride; in acetone soln., the first addition of the thiocyanate produces a precipitate which clears up on adding more reagent, with excess, potassium chloride is precipitated; ammonium thiocyanate gives a precipitate of ammonium chloride in acetone and pyridine soln.; in methyl acetate soln., similar results are obtained with potassium and ammonium thiocyanates. H. Moissan and S. Smiles reduced mercuric to mercurous chloride by heating it to 50° or 60° with amorphous **silicon**. According to A. Colson, **silicon sulphide** when heated with mercuric chloride forms silicon chloride SiCl_4 . O. Ruff and K. Albert found that **silico chloroform** is decomposed catalytically by mercuric chloride at 150°; and M. Phillips, that **copper silicide**, Cu_7Si_2 , is decomposed.

J. L. Gay Lussac and L. J. Thénard²¹ reported that mercuric chloride is reduced to the metal when heated with **potassium** or **sodium**. S. Kern, and K. Seubert and A. Schmidt found that when mercuric chloride vapour is passed over molten **magnesium**, some mercury is formed which partly amalgamates with the magnesium. According to A. Cossa, **aluminium** reduces the vapour of mercuric chloride with the evolution of heat. According to F. Capitaine, the metals **bismuth**, **zinc**, **tin**, **iron**, **nickel**, **lead**, and copper decompose mercuric chloride, forming mercurous chloride or metallic mercury which may form an amalgam with the excess of metal—for example, calomel and stannous and stannic chlorides; and, according to N. W. Fischer, **silver** forms a sublimate of mercurous chloride and a residue of silver chloride. According to N. W. Fischer most metals—nickel, copper, iron, zinc, cadmium, bismuth, **platinum**, **iron**, etc.—precipitate mercurous chloride or mercury or both from aq. soln. Mercury can be completely precipitated by magnesium from aq. soln. of mercuric chloride; H. Rose found that zinc likewise reduces mercury from the same soln. and amalgamation occurs if the soln. is acid; **cadmium** likewise forms needle-like crystals of amalgam. According to S. Peck, iron—*ferrum reductum*—forms mercurous chloride, and N. W. Fischer says that iron precipitates metallic mercury. The reaction is represented $\text{HgCl}_2 + \text{Fe} = \text{FeCl}_2 + \text{Hg}$, and it has been employed for detecting the presence of free iron in the presence of ferrous oxide. According to E. D. Campbell and S. C. Babcock,

mercuric chloride soln. dissolve a little phosphorus and iron in steel, and, according to J. B. J. D. Boussingault, the action is fairly rapid if the iron be suspended by platinum wire. According to R. Varet, nickel produces a little mercury, and mercuric chloride; and, according to M. C. Lea, G. Wetzlar, and A. Vogel finely-divided **silver** forms silver and mercurous chlorides; according to R. Schiff, **palladium** charged with hydrogen reduces mercuric chloride; according to H. Moissan, **chromium** powder is oxidized; and, according to W. C. Reid, **thallium** reduces mercuric salts to mercurous salts and mercury. A. Vogel, M. Cauval, and K. Heumann found that when a strip of **copper** is immersed in a soln. of mercuric chloride, mercury and cuprous chloride are precipitated: $\text{HgCl}_2 + 2\text{Cu} = 2\text{CuCl} + \text{Hg}$. If the soln. be acidified with hydrochloric acid, the copper is immediately covered with a white metallic film. H. Reinsch said that no change is perceptible when a strip of copper is immersed in a soln. containing one part of the salt in 5000 parts of water, but if the soln. be boiled, the copper acquires a golden-yellow colour, while if hydrochloric acid be present a grey film appears which, under the microscope, appears to be composed of minute globulets of mercury. The film is visible if but one part of salt is present in 15,000 parts of water. If the copper foil be dried, the grey film when rubbed becomes as bright as silver. Copper, zinc, aluminium, and tin rapidly precipitate mercury and mercurous chloride from soln. of mercuric chloride in benzonitrile; the action is slow with magnesium, iron, antimony, bismuth, nickel, and lead; mercury precipitates mercurous chloride; silver forms a mixed precipitate of silver and mercurous chlorides; arsenic, gold, and platinum have no action. The metals copper, magnesium, zinc, lead, **antimony**, and bismuth precipitate a mixture of mercurous chloride, and mercury from soln. of mercuric chloride in ethyl acetate; mercury and cadmium give mercurous chloride; silver a mixture of mercurous and silver chlorides; iron gives a precipitate of ferrous chloride; nickel, **cobalt**, **arsenic**, **gold**, and platinum have no action. Again, zinc, bismuth, and aluminium rapidly precipitate mercurous chloride and mercury from soln. of mercuric chloride in methylal; the action is slow with copper, nickel, magnesium, cadmium, and lead; silver gives a small precipitate of mercury and mercurous chloride; iron and mercury give a precipitate of mercurous chloride; while arsenic, gold, and platinum have no action. Soln. of mercuric chloride in acetone are not reduced by arsenic, antimony, lead, cobalt, and silver; cadmium, copper, nickel, mercury, and tin form mercurous chloride; while magnesium, zinc, iron, aluminium, and bismuth give mercury and mercurous chloride.

H. Rose²² said a soln. of **ferroussulphate** does not precipitate mercurous chloride; but ferrous salts generally reduce mercuric salts in darkness; the precipitation of mercurous chloride, according to C. Winther, is hindered by the presence of ferric salts. A. Mailhe said that **nickelous hydroxide** is not affected in the cold, but when heated, some is dissolved. W. Gibbs found mercuric salts were reduced by **ammonium phosphomolybdate**. S. M. Jörgensen found **chloropurpureochromic chloride** and some complex **cobalt salts** give precipitates with mercuric chloride. Mercuric chloride gives a brick-red precipitate of mercurous chromate when treated with soluble normal **chromates**, but not with dichromates.

When dry mercuric chloride is heated with the **alkali hydroxides or carbonates**, a sublimate of mercury and a residue of alkali chloride is formed—in the former case oxygen, and in the latter case carbon dioxide is given off. As C. F. John,²³ and K. Voit have shown, when a hydroxide of the alkalis or alkaline earths is added to a soln. of mercuric chloride, a reddish-brown precipitate of a basic chloride, $\text{Hg}_3\text{O}_2\text{Cl}_2$, or Hg_2OCl_2 , is formed provided the mercuric salt be in excess: $2\text{HgCl} + 2\text{KOH} = 2\text{KCl} + \text{H}_2\text{O} + \text{HgCl}-\text{O}-\text{HgCl}$; or else $3\text{HgCl}_2 + 4\text{KOH} = 4\text{KCl} + 2\text{H}_2\text{O} + \text{Hg}_3\text{O}_2\text{Cl}_2$; whereas if the alkali be in excess, yellow mercuric oxide is precipitated: $\text{HgCl}_2 + 2\text{KOH} = 2\text{KCl} + \text{H}_2\text{O} + \text{HgO}$. H. Lescœur represents the system as acquiring a state of equilibrium: $\text{HgCl}_2 + 2\text{KOH} \rightleftharpoons 2\text{KCl} + \text{HgO} + \text{H}_2\text{O}$; and, as shown by M. Lehmann, the basic salts and mercuric oxide are readily soluble in acids. L. Vignon, C. Arnold, W. Herz, and H. Debray have studied the character

of the precipitate produced under different conditions. K. Voit found that if alkali chlorides are present, the soln. can be made alkaline with sodium hydroxide without the formation of a precipitate; in the presence of ammonium chloride, the precipitate by the alkali hydroxides resembles that produced by aqua ammonia alone. According to L. Dobbin, when a mixture of mercuric chloride with potassium iodide and ammonium chloride is treated with alkali hydroxide, a yellow or brown coloration is produced, but not when treated with alkali carbonate. H. Vitenet found that the **hydrocarbonates** in ordinary water give a small precipitate with a soln. of mercuric and ammonium chlorides. The precipitation is also influenced by the presence of organic compounds—in the presence of conc. acetic acid, for example, A. Vogel found the precipitation is slow and incomplete and with sugar, or gum arabic, lime-water gives no precipitate unless, as F. W. Flashof and A. W. Buchner showed, the soln. has stood a long time. C. H. Pfaff, and P. L. Geiger found **magnesium oxide** or **calcium oxide** precipitates mercuric oxide, but not, according to A. Mailhe, if alkali chlorides be present. K. Haack said that barium oxide precipitates mercuric oxide from boiling soln. of mercuric chloride. According to A. Naumann, magnesium oxide; sodium bicarbonate; calcium oxide, hydroxide or carbonate; barium, strontium or magnesium carbonate, and potassium hydroxide, are without action on soln. of mercuric chloride in methylal; potassium carbonate gives a yellow soln. A soln. of mercuric chloride in benzonitrile is coloured yellow, and mercuric carbonate or oxide separates out when the soln. is treated with sodium or potassium hydroxide, and potassium carbonate; while sodium carbonate or calcium oxide, hydroxide or carbonate has no visible action.

H. Rose,²⁴ R. Schindler, and C. Winckler, noted that when treated with **alkali carbonates**, a soln. of mercuric chloride first becomes turbid, then reddens, and finally precipitates a reddish-brown basic carbonate, $\text{HgCO}_3 \cdot 3\text{HgO}$, that is:

Alkali-hydrocarbonates precipitate various oxychlorides from soln. of mercuric chloride. According to H. Arctowsky, **barium carbonate** precipitates a basic salt in the cold with mercuric nitrate but not with the chloride. According to L. L. de Koninck, barium carbonate usually acts only on those salts which can be more or less decomposed hydrolytically by water so as to form a basic salt and free acid. The barium carbonate acts by neutralizing the free acid and leaves the water still further to react with the salt. P. L. Geiger also found an excess of **magnesium carbonate** gives a reddish-yellow precipitate with soln. of mercuric chloride. According to K. Thümmel, ammonium carbonate soln. give a yellow precipitate of an ammine oxychloride, $\text{HgCl}_2 \cdot \text{HgO} \cdot 2\text{NH}_2\text{HgCl}$. According to M. Dukelsky, the **borates** of the alkalies and alkaline earths, magnesia, and magnesium hydroxide or carbonate give a precipitate of mercuric oxychloride, but not of mercuric oxide.

According to F. Diacon,²⁵ soln. in **alcohol** reduce mercuric to mercurous chloride, and the action is faster the greater the number of hydroxyl groups in the mol., for example, **mannite** is carbonized at 140° . According to J. Davy, and P. F. G. Boullay, the soln. in aq. alcohol—not absolute alcohol or ether—is reduced to mercurous chloride in sunlight, while a soln. in turpentine oil is not affected by light. E. Feider found **aldehydes**—e.g. **formaldehyde**—reduce mercuric chloride soln. to mercury. According to P. A. von Bonsdorff, **potassium formate** at 50° – 80° reduces mercuric to mercurous chloride, and with protracted boiling mercury is formed; and, according to J. W. Döbereiner, and F. L. Winckler, a boiling soln. of **sodium formate** reduces mercuric to mercurous chloride, but not to mercury. The reaction was proposed to M. Portes and M. Ruyssen, as a method for the quantitative determination of the formates and formic acid, but A. Scala showed that the reaction is not quantitative in the presence of acetic and butyric acids; and A. Lieben, that a large excess of mercuric chloride is needed, and the mixture must be heated 6–8 hrs. on a water-bath. H. Rose showed that the presence of various

chlorides or of acetic acid retards the speed of the reduction. A. Findlay and M. J. P. Davies showed that the reaction is of the second order, and the velocity determinations agree with: $2\text{HgCl}_2 + \text{H.COO}\text{Na} = 2\text{HgCl} + \text{NaCl} + \text{HCl} + \text{CO}_2$; and it is therefore inferred that the reduction takes place in stages. G. A. Linhart and co-workers explain the reduction by the same hypothesis as that employed for the reduction with phosphorous acid—*q.v.* N. R. Dhar said that the oxidation of sodium formate is unimolecular with respect to both substances, and the whole reaction is bimolecular. When exposed to light, mercuric chloride is reduced by **oxalic acid** or the **alkali oxalates** to mercurous chloride—with **ammonium oxalate**, ammonium chloride and carbon dioxide are formed at the same time. The sat. soln. do not react in darkness. The reduction by ammonium oxalate is faster in vacuo, or in an atm. free from oxygen. N. R. Dhar showed that the reaction $2\text{HgCl}_2 + \text{K}_2\text{C}_2\text{O}_4 = 2\text{KCl} + 2\text{CO}_2 + 2\text{HgCl}$ is induced by sunlight, the light from a carbon arc, a quartz mercury vapour lamp, or an arc between electrodes of thoria and zirconia. A. Jodlbauer and H. von Tappeiner said that the reaction is accelerated by fluorescent substances—fluorescein, anthracene, anthraquinone disulphonate, acridine, benzo-flavine, phenylquinaldine, quinine, æsculine, and by hydrogen; and J. H. Kastle and W. A. Beatty say that it is accelerated by 0.000000,0195 grm. of potassium permanganate, by 0.000000,016 grm. of ferric chloride, or by other oxidizing agents, but slackened by potassium chromate. N. R. Dhar studied the reduction of mercuric chloride with oxalic, **tartaric**, **malic**, **malonic**, **glycollic**, and **citric acids**. Malonic acid acts more slowly than oxalic acid. According to E. Rupp and A. B. Dott, tartaric acid reduces mercuric chloride in the presence of manganese dioxide; **potassium tartrate** reduces mercuric to mercuric chloride in darkness and in light; the reaction is accelerated by heat. The white of an egg or **albumin** gives a white sparingly soluble precipitate with mercuric chloride, and hence its use as an antidote for corrosive sublimate. J. B. Kämmerer²⁶ found that between 30° and 40° the white of an egg also reduces some mercuric to mercurous chloride. J. Müller found the presence of sodium chloride retards the precipitation. According to T. Gayda, the thermal value of the reaction is 14.3 cal. per grm. of albumin, and is independent of the vol. of the soln. According to M. Siegfried, a soln. of **gelatine** gives a precipitate with a soln. of mercuric chloride, and the filtrate furnishes crystals of mercurous chloride after standing for some time, and **glycocoll** behaves similarly, precipitating crystals of mercurous chloride in about ten days. J. B. Nevins says an aq. soln. of one part of corrosive sublimate and 160 parts of **gum arabic** becomes turbid in a few hours, and in 6 days furnishes a small grey deposit, and he obtained analogous results with decoctions of various plants. F. Vulpus found **pepsin** also reduced mercuric to mercurous chloride. A. Vogel, and H. Ley, said that **sugar** precipitates mercurous chloride from a boiling soln. of mercuric chloride. Many organic compounds form addition compounds with mercuric chloride and a very great number of organo-mercury compounds have been reported. Mercuric chloride is one of the best of antiseptics, and it is used in aq. soln. 1 : 1000 or 1 : 4000. It enters into the composition of a number of medicinal preparations.

§ 13. Mercuric Oxychlorides—Basic Mercuric Chlorides

The hydrolytic action of water on aq. soln. of mercuric chloride has been previously discussed. In 1815, J. L. Proust¹ showed that some mercuric oxide dissolves when boiled with aq. soln. of mercuric chloride; the soln. becomes turbid on cooling, and deposits crystals of a mercuric oxychloride. In 1849, C. Roucher emphasized the fact that the composition of the oxychloride formed by the action of mercuric chloride soln. on mercuric oxide is different according as the yellow or red oxide is used, and likewise according to the temp. and nature of the solvent. A large number of mercuric oxychlorides—and in some cases isomeric forms—has been reported. They are produced by the action of red or yellow mercuric oxide on aq. or alcoholic soln. of mercuric chloride; by the incomplete precipitation of a soln. of the chloride by an alkali hydroxide, carbonate, or bicarbonate; by fusing together the oxide and chloride at about 300°; by the incomplete action of chlorine on mercuric oxide; or by the hydrolytic action of water on oxychlorides of low basicity. Nine compounds with $\text{HgCl}_2:\text{HgO}$ respectively as 2:1, 1:1, 2:3, 4:7, 1:2, 1:3, 1:4, 1:5, and 1:6 have been reported, and for some of these isomeric forms have been described. A. Driot said that the four oxychlorides 2:1, 1:1, 1:2, and 1:3 exist in soln. when mercuric oxide is boiled with an aq. soln. of mercuric chloride for eight hours—when 0.5 to 4.0 per cent. of the last-named salt is present, the 1:3 compound separates in yellow to black needles when the soln. cools; with 4.0 to 8.0 per cent. HgCl_2 , black rhombohedra of the 1:2 salt; with 30 per cent. HgCl_2 , a mixture of the 1:2 and 1:3 salts which can be separated by levigation from the 2:1 salt. He also prepared the 1:1 salt as indicated below. A. Driot made only one form of each of the four oxychlorides. K. Thümmel believed that only the five compounds 2:1, 1:1, 1:2, 1:3, and 1:4 really exist. E. P. Schoch omitted the 1:1 compound, and further supposed that isomeric forms of the 1:2, 1:3, and 1:4 forms exist. As in the case of the other basic chlorides, there is some uncertainty as to which of the oxychlorides are chemical individuals, and the uncertainty will remain until the conditions of stability have been thoroughly investigated in the light of the phase rule. S. Toda studied the system $\text{H}_2\text{O}-\text{HgCl}_2-\text{HgO}$, at 35°, and the results are summarized in Fig. 14, where N denotes $100m/(100+m)$ in the ratios $100m\text{H}_2\text{O}:x\text{HgCl}_2:(100-x)\text{HgO}$. Here there are only two oxychlorides 1:1, and 1:4. E. P. Schoch proposed naming the oxychlorides in such a way as to indicate by a numerical prefix the number of mercury and oxygen atoms in the simplified empirical formula. This is a temporary expedient until the constitution and mol. wts. are known.

C. Roucher prepared yellow cubic crystals of the 1:2 salt, **trimercuric oxychloride**, $\text{HgCl}_2 \cdot 2\text{HgO}$, or $\text{ClHg} \cdot \text{O} \cdot \text{Hg} \cdot \text{O} \cdot \text{HgCl}$, by dissolving as much finely divided mercuric oxide as possible in a boiling soln. of 30 to 35 grms. of mercuric chloride in 100 c.c. of water. The crystals which separate between 60° and 70° are dried, and then washed with ether. K. Thümmel, E. P. Schoch, and A. Driot employed somewhat similar processes. Indeed, according to the former, this compound is present in all soln. of mercuric chloride in which mercuric oxide has been dissolved,

and he added that if a conc. soln. of mercuric chloride be carefully poured over moist mercuric oxide at the bottom of a tall cylinder, white octahedral crystals of the 2:1 salt will grow above the black 1:2 salt.

FIG. 14.—Equilibrium relations in the System $\text{HgCl}_2\text{—HgO—H}_2\text{O}$, at 35° .

18.7 per cent. required for the 2:1 salt; but E. P. Schoch's products gave 18.4 to 18.56 per cent. of chlorine. S. Toda obtained no evidence of this compound at 25° .

A. Driot prepared a yellow amorphous powder of the 1:1 salt, **dimercuric oxychloride**, $\text{HgCl}_2\cdot\text{HgO}$, that is, HgCl—O—HgCl , by heating mercuric oxide for six days at 100° with an excess of a 30 per cent. soln. of mercuric chloride; or by the evaporation of a sat. soln. of mercuric oxide in mercuric chloride on a water-bath, and washing out the free mercuric chloride with alcohol. G. André says this salt cannot be obtained in the wet way, and he made it by heating 0.1 eq. of red mercuric oxide with rather more than 0.1 eq. of mercuric chloride in a sealed tube in an oil-bath. K. Haack made it as a yellow precipitate by mixing dil. or conc. soln. of mercuric chloride and disodium hydrogen phosphate in any proportion whatever; and he also made it by adding powdered mercuric chloride to molten disodium hydrogen phosphate. According to G. André, the heat of formation (HgO , HgCl_2) is 1.65 Cals. The salt gives yellow mercuric oxide when treated with potassium hydroxide. K. Thümmel supposed this salt existed in an aq. soln. of mercuric oxide in mercuric chloride, but he did not succeed in its isolation; he suggested that it might be regarded as the mercuric salt of the hypothetical acid, $\text{H}_2(\text{OHgCl}_2)$, namely, $\text{Hg}(\text{OHgCl}_2)$. S. Toda obtained this compound under the conditions indicated in Fig. 14. He said that it furnishes dark purple-red acicular crystals, and is probably the compound made by J. Volhard from mercuric chloride and sodium acetate, and by N. A. E. Millon, K. Thümmel, and E. P. Schoch from mercuric chloride and potassium carbonate.

The 2:3 salt was reported by G. André to be formed as an amorphous precipitate when a soln. of yellow mercuric oxide in a hot sat. soln. of magnesium chloride is cooled and then poured into a large excess of water. K. Voit made what he regarded as the 4:7 salt by gradually adding aq. sodium hydroxide to a dil. soln. of mercuric chloride—with the first addition, the soln. remains clear, then it becomes opalescent, and deposits a white flocculent precipitate which becomes yellow and then red on exposure to air. A soln. of sodium chloride restores the white colour. The white flocculent precipitate, dried at 100° , has a composition corresponding with $4\text{HgCl}_2\cdot 7\text{HgO}$.

the 2:1 salt will grow above the black 1:2 salt. According to K. Thümmel, the crystals have a sp. gr. 6.42 (27.5°). The salt is decomposed by warm water or cold alcohol, forming the red 1:2 salt; and with hot alcohol, the black 1:2 salt is formed. According to C. Roucher, potassium hydroxide gives a yellow precipitate, and, according to K. Thümmel, sodium hydroxide gives a red precipitate of mercuric oxide. N. Tarugi failed to prepare this salt according to C. Roucher's or K. Thümmel's directions, for the chlorine in the product he obtained varied between 16 and 21 per cent., and never came near the theoretical

If mercuric oxide be mixed with a 30 per cent. soln. of mercuric chloride, and kept for six days at 100° , the 1 : 1 salt is formed ; but with a 4-8 per cent. soln. of the chloride, black rhombohedral crystals of the 1 : 2 salt appear ; and if a 0.5 to 4 per cent. soln. of the chloride is used, yellow to black needle-like crystals of the 1 : 3 salt are formed. If the oxide be heated with the chloride in a sealed tube, the 1 : 2 salt appears. Red and black forms of the 1 : 2 salt, **trimercuric dioxychloride**, $\text{HgCl}_2 \cdot 2\text{HgO}$, have been reported. According to E. P. Schoch, the methods for preparing the two varieties are analogous except that for the black the liquid should be alkaline, and acid for the red. The *red variety* seems to have been first made by A. J. Balard by the action of calcium hypochlorite on mercury. N. A. E. Millon made it by the action of a cold sat. soln. of potassium bicarbonate on 6 to 10 times its volume of a soln. of mercuric chloride, sat. at 15° . G. André used a similar method. There are several modifications of N. A. E. Millon's process for making this salt, by adding a soln. of a normal or acid alkali carbonate to one of mercuric chloride : e.g., for each mol proportion of mercuric chloride, K. Thümmel used 1.375 of KHCO_3 , 0.667 to 2.0 of NaHCO_3 , or 0.1 to 0.167 of Na_2CO_3 in a boiling soln. The mother liquid should be promptly poured off the red precipitate or the colour changes to purple, violet or brown. E. P. Schoch heated an intimate mixture of mercuric oxide with half a mol. proportion of mercuric chloride for 6 to 8 hrs. in a sealed tube at 300° , and extracted the mass with anhydrous ether in Soxhlet's apparatus so as to remove the free mercuric chloride. If less mercuric chloride be used a mixture of the 1 : 2 and the 1 : 4 salts is formed. K. Haack made this salt by the action of disodium hydrogen phosphate on a soln. of mercuric chloride. H. Arctowsky heated in a large flask to 90° for 48 hrs. a 5 per cent. soln. of mercuric chloride with some pieces of marble. After removing the marble, the soln. was cooled slowly to 50° for the salt.

When an excess of mercuric oxide stands in contact with a dil. soln. of mercuric chloride, the *black variety* of trimercuric dioxychloride forms in the lower layers where the influence of the mercuric oxide is predominant ; it does not form in the upper layers. According to P. C. Ray, if a neutral soln. of mercurous nitrite, which is always contaminated with a little mercuric nitrite be treated with sodium chloride, mercurous chloride is precipitated, and if an excess of the salt soln. be used, the spontaneous evaporation of the filtrate furnishes a mixture of two oxychlorides of the same composition, $\text{HgCl}_2 \cdot 2\text{HgO} \cdot \frac{1}{2}\text{H}_2\text{O}$, but one is black, the other orange. Sodium hydroxide converts the black variety into the orange-coloured one. The black variety was made by M. Donovan, and P. Grouvelle by the action of red mercuric oxide on a soln. of mercuric chloride ; R. Phillips, K. Thümmel, E. P. Schoch, and A. Driot used a similar process. Thus, the last-named boiled a 4 to 8 per cent. soln. of mercuric chloride, sat. with mercuric oxide, for about 8 hrs., and filtered the hot liquid. On cooling the compound separated out. C. Roucher made it by the action of alcoholic soln. of mercuric chloride on mercuric oxide. H. Thaulow treated mercuric oxide with cold chlorine hydrate, or hypochlorous acid. J. Volhard made it by mixing a cold sat. soln. of mercuric chloride and sodium acetate. The liquid is alkaline, and after standing some days, crystals of the black compound appear along with a flocculent substance which is easily separated. A further crop of crystals is obtained by adding some potassium hydrocarbonate. J. S. van Nest hung a piece of marble in a 5 per cent. soln. of mercuric chloride heated on a water-bath for 48 hrs. at 70° ; and slowly cooled the liquid. K. Thümmel treated 10 parts of dry trimercuric dioxynitrate, $\text{Hg}(\text{NO}_3)_2 \cdot 2\text{HgO} \cdot \text{H}_2\text{O}$, for 3 hrs. with a soln. of 1.9 parts of potassium chloride ; the precipitate which is at first red changes to black. N. A. E. Millon made the black 1 : 2 salt by pouring one vol. of a cold sat. aq. soln. of potassium bicarbonate into three vols. of a soln. of mercuric chloride sat. at 15° , and on stirring with a glass rod black streaks appeared on the walls of the beaker. The liquid is poured from the beaker and a new mixture run in, and stirred. The precipitate which forms is washed with cold water, and dried over sulphuric acid. E. P. Schoch used an analogous process.

The red variety is coloured various shades of red, and, according to E. P. Schoch, it forms pyramidal crystals belonging to the hexagonal system, while, according to J. Blaas, the black variety, obtained by the prolonged action of dil. nitric acid on partially precipitated mercuric chloride, forms monoclinic prismatic crystals which, according to J. Volhard, have the axial ratios $a:b:c=0.9178:1:0.9978$, and $\beta=65^{\circ}30'$. J. S. van Nest gave rather different measurements for a sample prepared by the calcium carbonate process—viz. $a:b:c=1.9728:1:1.0452$, $\beta=125^{\circ}57'$. E. P. Schoch gave for the sp. gr. of the red variety 8.16 to 8.43 (27.5°); and for the black variety, 8.53; for the black variety also J. Volhard gives 8.670 (17°); J. S. van Nest, 8.286; and J. Blaas, 8.63, and hardness 2.5. Neither compound is affected by water at ordinary temp. Potassium or sodium hydroxide gives yellow mercuric oxide with the red variety; and red mercuric oxide with the black variety. Alkali carbonates and chlorides readily attack the red variety in the cold, but not the black variety even on boiling. According to M. C. Lea, the red variety is darkened by the application of a high press. G. André gives the heat of formation ($\text{HgCl}_2, 2\text{HgO}$) as 3.15 Cals. N. Tarugi believes that both varieties are only mixtures because of the variability in the analyses of different preparations. S. Toda obtained no evidence of the existence of this compound in his study of the ternary system $\text{HgCl}_2\text{—HgO—H}_2\text{O}$, at 35° .

According to W. F. Hillebrand and W. T. Schaller, the mineral *kleinite* from Terlingua (Texas) has the composition 85.86 per cent. Hg; 7.30 per cent. Cl; 3.10 per cent. SO_4 ; 2.57 per cent. N; and 1.03 per cent. H_2O , and it is thought to be a mixture of a mercury ammonium chloride, NH_2HgCl , with a smaller amount of mercury sulphate or oxysulphate. A. Sachs' analyses of a mineral from Breslau corresponded with the formula for **tetramercuric trioxychloride**, $\text{HgCl}_2.3\text{HgO}$, and he regarded the nitrogen and sulphuric acid, also present, *als Beimengung nicht als integrierende Bestandtheile des Minerals*. W. F. Hillebrand also found minute octahedral crystals of *mosesite*, a canary-yellow mineral analogous in composition and properties to *kleinite*, on calcite from Terlingua (Texas). The crystals of *kleinite* are hexagonal with $a:c=1:1.6642$. The sp. gr. of the orange crystals of *kleinite* is 7.96 to 7.99 and of the yellow crystals 7.94 to 8.04. The hardness is between 3 and 4. The crystals of *kleinite* and *mosesite* are optically birefringent, but they become isotropic respectively at 194° and 184° ; on cooling, they slowly revert to the birefringent form. The mean refractive index of *kleinite* is 1.8. The crystals of *mosesite* are slowly changed to calomel by hydrochloric acid; *kleinite* is slowly dissolved. There is no perceptible sublimate when *kleinite* is heated to 260° , for many hours, but between 260° and 280° , a sublimate of calomel and mercury appears.

Tetramercuric trioxychloride, $\text{HgCl}_2.3\text{HgO}$, has been reported in yellow crystals of prismatic and tabular habits, as a yellow and as a brick-red amorphous powder. E. P. Schoch made *yellow prismatic crystals* of $\text{HgCl}_2.3\text{HgO}$ by shaking together for ten minutes a mixture of freshly precipitated mercuric oxide with a cold sat. soln. of mercuric chloride in proportions not exceeding two mols of the latter to one of the former. After decanting off the liquid, the residue was dried on a porous tile, and washed with absolute ether. If ordinary powdered and levigated yellow or red mercuric oxide be employed, as recommended by K. Thümmel, the product agrees with $\text{HgCl}_2.3\text{HgO}$, containing much free oxide. A. Driot made the same compound by saturating with mercuric oxide a boiling soln. with between 0.5 and 4 per cent. of mercuric chloride. After boiling 8 hrs. the mixture was filtered rapidly and the crystals of $\text{HgCl}_2.3\text{HgO}$ which first separate are followed by those of the salt in question. These are washed with alcohol. N. A. E. Millon made *yellow tabular crystals* by pouring a cold soln. of mercuric chloride, sat. at 15° , into an equal volume of a sat. soln. of potassium bicarbonate; G. André employed an analogous process; he mixed equal volumes of cold sat. soln. of mercuric chloride and potassium bicarbonate; J. S. van Nest poured soln. of mercuric chloride and potassium bicarbonate in the mol. proportion 8:11 into about a litre of water at 85° . H. Arctowsky heated two

litres of a 5 per cent. soln. of mercuric chloride for a month at 80°, and cooled the soln. every evening; if the temp. be 97° he said the compound is not formed. C. Roucher reported citron-yellow amorphous powders to be formed by the action of mercuric oxide on a soln. of mercuric chloride, but K. Thümmel says it is a mistake to suppose these powders amorphous, they are crystalline. P. Grouvelle, K. Voit, N. A. E. Millon, and G. André have also described brick-red amorphous powders obtained by the action of alkali hydroxides or carbonates, or calcium chloride on mercuric chloride. K. Haack made them by the action of a soln. of sodium chloride on mercuric phosphate, or a mixture of mercuric and an alkali chloride. The red powder probably differs from the yellow, merely in the size of grain.

N. Tarugi suggested that all these processes for preparing the compound $\text{HgCl}_2 \cdot 3\text{HgO}$ give mixtures of mercuric oxide and chloride in indefinite proportions because instead of the theoretical 7.72 per cent. of chlorine, the yellow crystalline substance prepared in different ways contained from 3.8 to 7.9 per cent. of chlorine; the yellow amorphous powder, 2.9 to 6.2 per cent. of chlorine; and the brick-red powder 3.6 to 8.1 per cent. of chlorine. He added that he prepared small yellow crystals of definite composition by placing small cubes of white statuary marble of a sugar-like texture in a sat. soln. of mercuric chloride at 15°; the crystals which were formed in 15 to 20 days were separated, washed in hot water, and dried in vacuo. This process is analogous to that employed by R. Phillips in 1830. According to E. P. Schoch, the yellow prisms have a sp. gr. 7.93 (27.5°). The compound is not changed by light, by heating to 110°, or by boiling with a 7 per cent. soln. of mercuric chloride; with an excess of mercuric chloride it forms $2\text{HgCl}_2 \cdot \text{HgO}$. According to E. P. Schoch, when heated with water it forms yellow plates of $\text{HgCl}_2 \cdot 4\text{HgO}$; and, according to K. Thümmel, alkali carbonates and chlorides also transform it into the 1:4 salt; boiling with mercuric oxide does the same thing; and alcohol decomposes it, forming mercurous chloride. According to G. André, the heat of formation of the yellow plates is $(\text{HgCl}_2, 3\text{HgO})$, 3.95 Cals. N. Tarugi said that when heated, or boiled with water or alkali soln., this oxychloride is decomposed into its constituents, while dil. nitric acid converts it into a white amorphous powder. S. Toda obtained no evidence of this compound in his study of the ternary system $\text{HgCl}_2\text{—HgO—H}_2\text{O}$, at 35°.

A. F. de Fourcroy and L. J. Thénard obtained a precipitate by adding a small amount of potassium hydroxide to a soln. of mercuric chloride, and, according to G. André, the product when dried at 100° is an amorphous brown powder of **penta-mercuric tetraoxychloride**, $\text{HgCl}_2 \cdot 4\text{HgO}$. K. Thümmel made the same product by treating a sat. soln. of mercuric chloride with normal or acid alkali carbonate—say one mol of HgCl_2 with 30 to 35 of KHCO_3 . N. A. E. Millon also made this product by boiling the amorphous 1:2 or 1:3 salts with water. The crystalline variety is made, according to H. Arctowsky, by heating 2 litres of a 5 per cent. soln. of mercuric chloride for a month at 100° allowing the soln. to cool in the evening; the yield is 25 per cent. He also made the same crystals by leaving pieces of marble in a 10 per cent. soln. of mercuric chloride at 39° for three months. G. André made it by heating for 7 hrs. to near the b.p. red mercuric oxide with four times as much mercuric chloride in aq. soln.—analogous methods were employed by E. P. Schoch, H. Thaulow, and K. Thümmel. According to E. Soubeiran, if an excess of an alkali carbonate soln. be added to a soln. of mercuric chloride, a red precipitate is formed, and nearly all the mercury is removed from the soln.; but if insufficient alkali carbonate be added to precipitate all the mercury, the red powder at first precipitated changes to brown crystals. If the soln. of mercuric chloride be previously mixed with sodium chloride so as to produce a less easily decomposable double salt, a white turbidity first appears on the addition of the alkali carbonate, and the brown crystals eventually separate. The formation of these crystals is accelerated by heat since the excess of carbon dioxide is expelled from the alkali carbonate and its decomposing action on the mercuric chloride prevented; but if the temp. exceeds 40°, the precipitate will be mixed with free mercuric oxide.

K. Thümmel, N. A. E. Millon, and J. S. van Nest used analogous modes of preparation. M. Dukelsky and J. S. van Nest substituted a dil. soln. of borax for the alkali carbonate. K. Thümmel also made the same crystalline product by the action of potassium bicarbonate on the crystalline 1:1, 1:2, or 1:3 salt; and N. A. E. Millon obtained it by the action of water on the two last-named salts. S. Toda studied the conditions of formation of this compound, Fig. 14, and it appeared as a brownish-yellow substance, amorphous to the naked eye. According to E. P. Schoch, this salt forms hexagonal plates, reddish-brown or black in colour, and of sp. gr. 8.008 to 8.170 at 27.5°. G. André says the heat of formation of all varieties ($\text{HgCl}_2 \cdot 4\text{HgO}$) is 9.86 Cals. According to N. A. E. Millon and K. Thümmel, alkali hydroxides give red mercuric oxide; alkali bicarbonates have no action; it is soluble in acids, insoluble in alcohol and ether. There are some differences in the reports of the composition of the black shining crystals; for instance, O. B. Kühn gave $2\text{HgCl}_2 \cdot 5\text{HgO}$; H. Thaulow, $\text{HgCl}_2 \cdot 4\text{HgO}$; and P. Grouvelle, $\text{HgCl}_2 \cdot 5\text{HgO}$. According to N. Tarugi, identical products cannot be obtained by any of the given methods of preparation, for they have a variable composition, and cannot therefore be chemical individuals.

C. Roucher and K. Thümmel have reported the 1:5 salt, *hexamercuric pentoxychloride*, $\text{HgCl}_2 \cdot 5\text{HgO}$, by allowing a soln. of mercuric chloride to stand in contact with mercuric oxide; and the 1:6 salt, *heptamercuric hexa-oxychloride*, $\text{HgCl}_2 \cdot 6\text{HgO}$, by the action of an excess of mercuric oxide on cold mercuric chloride dissolved in water frequently renewed, form $\text{HgCl}_2 \cdot 6\text{HgO} \cdot \text{H}_2\text{O}$; but, by using a larger quantity of chloride, the anhydrous salt is produced. Neither of these basic chlorides is so well-defined as those which precede, and S. Toda obtained no evidence of their existence in his study of the system $\text{HgCl}_2\text{—HgO—H}_2\text{O}$, at 35°; but the oxychloride 1:4 forms solid soln. with mercuric oxide.

§ 14. Mercuric Ammino-chlorides

Amidogen, NH_2 , can combine with the metals. The metal amides have a remarkable tendency to unite with the chlorides or oxides of the same metal or a metal of the same family to form compounds which resemble the oxychlorides, sulphochlorides, or oxysulphides. . . . Ammonia, NH_3 , that is, hydrogen amide, H.NH_2 , can play the same part as water, hydrogen oxide, either as basic water or as water of crystallization. It can equally well replace the water to which T. Graham applied the term saline water.—R. J. KANE (1839).

In addition to the *double salts* of mercury and ammonium which are analogous with the double salts of mercury with salts of potassium and the other basic metals,

there is a series of *ammino-compounds*¹ in which ammonia, NH_3 , plays the part of the water of crystallization in the salts of mercury; another series of *ammonio-basic salts* in which aminolysis analogous with hydrolysis has occurred, and which is typified by the reaction: $\text{HgCl}_2 + 2\text{NH}_3 \rightleftharpoons \text{NH}_2.\text{Hg}.\text{Cl} + \text{NH}_4\text{Cl}$, analogous with $\text{HgCl}_2 + \text{H}_2\text{O} \rightleftharpoons \text{HO}.\text{Hg}.\text{Cl} + \text{HCl}$. Just as the hydrolysis of the chlorides is retarded by hydrochloric acid so is their aminolysis retarded by the presence of ammonium chloride. There is still another series of mixed *aquobasic salts* or *ammino-basic salts* in which both aminolysis and hydrolysis have occurred, and it may be typified by the aminolytic reaction: $\text{HgCl}_2 + 2\text{NH}_3 \rightleftharpoons \text{NH}_2.\text{Hg}.\text{Cl} + \text{NH}_4\text{Cl}$, followed by the hydrolytic reaction: $2(\text{NH}_2.\text{Hg}.\text{Cl}) + \text{H}_2\text{O} \rightleftharpoons \text{NH}_4\text{Cl} + \text{ClHg}.\text{NH}.\text{HgOH}$.

G. Gore,² E. C. Franklin and C. A. Kraus, and F. M. G. Johnson and N. T. M. Wilsom find mercuric chloride to be soluble in *liquid ammonia*; the two unite to form a series of addition products—*ammino-chlorides*—in which the ammonia behaves in an analogous manner to water in salts containing water of crystallization. Similarly, H. D. Gibbs said that mercuric chloride unites with liquid *methylamine*, forming a white addition product which is but sparingly soluble. According to P. Grouvelle (1821), and H. Rose (1830), ammonia gas is slowly absorbed by mercuric chloride at ordinary temp.—5.75 per cent. in two days—the absorption is more rapid if the salt be warmed, and if melted and then cooled in this gas, the salt takes up 6.8 per cent. of ammonia. The product thus corresponds with mercuric monammino-chloride, $\text{HgCl}_2.\text{NH}_3$. The six ammino-salts of mercuric chloride which have been reported have the ratio $\text{HgCl}_2 : \text{NH}_3$ as 1 : 1, 2 : 3, 1 : 2, 1 : 3, 1 : 4, and 1 : 12. The 3 : 2 salt—**trimercuric diamminochloride**, $3\text{HgCl}_2.2\text{NH}_3$ —reported by D. Strömholm, as a product of the action of ammonia on an almost sat. soln. of mercuric chloride in ether, is generally regarded as a mixture. It was, however, prepared by M. C. C. Holmes by a digesting at 100° infusible precipitate in a soln. of 47 grms. of ammonium chloride and 65–130 grms. of mercuric chloride. The crystals obtained on cooling the filtered soln. were washed twice with alcohol, twice in ether, and left in vacuo for some hours.

The product of the action of a current of ammonia gas on heated mercuric chloride, or that obtained by volatilizing a mixture of mercuric oxide and ammonium chloride, was supposed by R. J. Kane to be **mercuric monamminochloride**, $\text{HgCl}_2.\text{NH}_3$ —*vide supra*. E. Mitscherlich³ prepared the same compound by sublimation from a mixture of mercuric oxide and ammonium chloride; and G. André, by the gradual addition of a soln. of mercuric chloride to an ammoniacal soln. of ammonium chloride so as to avoid a rise of temp. The curdy precipitate is washed by decantation with cold water until it loses the smell of ammonia, and then dried at 100° . A. Naumann made it by passing an excess of ammonia gas into a soln. of mercuric chloride in benzonitrile. This compound melts when heated, and sublimes without much loss of ammonia; it is insoluble in water, but is decomposed by prolonged contact with hot water, forming a yellow substance. According to R. J. Kane, it is resolved by water into soluble alembroth salt and insoluble infusible white precipitate: $2(\text{HgCl}_2.\text{NH}_3) = \text{NH}_2.\text{Hg}.\text{Cl} + \text{NH}_4\text{HgCl}_3$. L. Pesci believed the alleged monoammine to be most probably a mixture.

R. Varet claims to have made *mercuric sesquiammino-chloride*, $2\text{HgCl}_2.3\text{NH}_3$, by the action of ammonia gas at 0° on mercuric chlorocyanide, HgClCy ; R. Jarry also supposed this compound to be present in ammoniacal soln. of mercuric chloride.

There have been many attempts to explain the composition of *fusible white precipitate* or the white precipitate—*mercurius precipitatus albus*—of the pharmacopœia, and the systematic name applied to the compound has changed with the fashion for representing its composition in a particular way. Thus, its ultimate composition corresponds with $\text{HgCl}_2.2\text{NH}_3$, and C. F. Rammelsberg,⁴ and L. Pesci arranged the symbols to $3\text{NH}_4\text{Cl}.\text{NH}_2\text{Hg}_2\text{Cl}$, which makes it appear as a double *ammonium dimercuriammonium chloride*. H. Gaudech on arranged the symbols $2\text{HCl}.\text{NHg}_2(\text{NH}_3)_3\text{Cl}$; K. A. Hofmann and E. C. Marburg, $\text{Hg}(\text{NH}_3\text{Cl})_2$,

mercuridiammonium chloride; and H. Fürth, $\text{NH}_3\text{Cl.Hg.NH}_3\text{Cl}$, or else as $\text{Cl.Hg.NH}_3\text{Cl}$. According to E. C. Franklin, it may be formulated as $\text{HgCl}_2.2\text{NH}_3$, or $\text{Hg}(\text{NH}_3)_2\text{Cl}_2$, where the ammonia is united as ammonia of crystallization. This latter view makes the name **mercuric diammino-chloride**.

Mercuric diammino-chloride was made by E. Mitscherlich by slowly adding a soln. of mercuric chloride to a boiling ammoniacal soln. of ammonium chloride so long as the precipitate redissolves; the rhombohedral crystals of the salt—possibly contaminated with a little infusible white precipitate, $\text{NH}_2.\text{Hg.Cl}$ —separate out on cooling. D. Strömholm used an analogous process. C. F. Rammelsberg made this salt by dissolving freshly precipitated mercuric oxide in an ammonium chloride soln. and treating the liquid with aqua ammonia. G. André, H. Gaudechon, and K. A. Hofmann and E. C. Marburg employed an analogous process. According to G. André, the curdy precipitate can be obtained in a crystalline form by heating with ammonia to 200° in a sealed tube. P. L. Geiger has stated that a cold soln. of ammonium chloride has no action on red mercuric oxide, but that a hot soln. the colour of the red oxide changes to yellow, provided that the soln. contains approximately one part of ammonium chloride for every four parts of mercuric oxide; while if about one part of ammonium chloride is present for every two parts of oxide, infusible white precipitate is formed; and, added L. Gmelin, fusible white precipitate is produced if an excess of ammonium chloride be present. P. Geiseler made this compound by adding sodium or potassium carbonate, in not too great an excess, to a cold aq. soln. of equal parts of mercuric and ammonium chlorides—every 100 parts of the mercuric chloride required 191 parts of crystallized sodium carbonate for complete precipitation, and yielded 103.2 parts of the well-dried precipitate—1.4 parts of mercury remained in soln. If about $3\frac{1}{2}$ times as much sodium carbonate be used for the precipitation, the precipitate when washed acquires a yellow tinge, but recovers its whiteness when washed with a soln. of sal-ammoniac. A. Duflos, G. Krug, K. Thümmel, and C. H. Hirzel obtained similar results with ammonium carbonate. L. Pesci, C. F. Rammelsberg, G. Krug, and R. J. Kane converted mercuric amidochloride, $\text{NH}_2.\text{Hg.Cl}$; dimercuriammonium chloride, $\text{NH}_2.\text{Hg}_2\text{Cl}$; and the chloride of Millon's base, HO.Hg.NH.Hg.Cl , into mercuric diammino-chloride by treatment with a soln. of ammonium chloride. According to E. Vogt, and A. Naumann, mercuric diammino-chloride is precipitated when dry ammonia is passed into a cold soln. of mercuric chloride in acetone; in pyridine (J. Schröder); in ethyl acetate (A. Naumann, M. Hamers, and E. Alexander); in methyl acetate (F. Bezold); and in methylal (W. Eidmann).

Mercuric diammino-chloride forms small rhombohedral crystals. According to A. Duflos, the precipitate is not altered by heating it to 135° ; it gives ammonia and a white sublimate at 180° ; and at 300° , it fuses to a clear colourless liquid which, according to F. Wöhler, gives off nitrogen and ammonia and then sublimes. The sublimate when treated with water leaves a residue of mercurous chloride, and a soln. of mercuric and ammonium chlorides. According to G. Krug and K. Vahle, if the heating be stopped when the evolution of ammonia has ceased, the molten mass congeals to a reddish-brown fibrous mass. According to E. Alexander, when heated in a sealed tube, ammonia is first evolved, and mercuric chloride sublimes. Mercuric diammino-chloride is stable in water only in the presence of a great excess of ammonium chloride, and when treated with water, it is first converted into fusible white precipitate: $\text{HgCl}_2.2\text{NH}_3 \rightleftharpoons \text{NH}_2.\text{Hg.Cl} + \text{NH}_4\text{Cl}$, and finally, after long washing into the chloride of Millon's base: $2(\text{NH}_2.\text{Hg.Cl}) + \text{H}_2\text{O} \rightleftharpoons \text{HO.Hg.NH.Hg.Cl} + \text{NH}_4\text{Cl}$, and hence H. Gaudechon says that boiling water decomposes it into ammonia and mercuric chloride; R. J. Kane, into the yellow compound the chloride of Millon's base, $\text{NH}_2.\text{Hg.O.Hg.Cl}$, or HO.Hg.NH.Hg.Cl . The last stage of the reaction is: $\text{HO.Hg.NH.Hg.Cl} + \text{H}_2\text{O} \rightleftharpoons 2\text{HgO} + \text{NH}_4\text{Cl}$. The reactions are reversible, and hence the action of water on mercuric diamino-chloride can be reversed, for by digesting mercuric oxide with ammonium chloride, the chloride of Millon's base, HO.Hg.NH.Hg.Cl , is first formed; then infusible white precipitate, $\text{NH}_2.\text{Hg.Cl}$;

and finally, $\text{HgCl}_2 \cdot 2\text{NH}_3$. According to F. A. Flückiger, and C. H. Hirzel iodine converts mercuric diammino-chloride into mercurous and mercuric chlorides, mercuric iodide, nitrogen, and ammonia: $2\text{I}_2 + 6\text{Hg}(\text{NH}_3)_2\text{Cl}_2 = \text{N}_2 + 6\text{NH}_4\text{Cl} + 4\text{NH}_3 + 2\text{HgCl}_2 + 2\text{HgI}_2 + 2\text{HgCl}$. Mercuric diammino-chloride is readily dissolved by acids; and K. Dieterich says if it has been dried below 30° it is soluble in cold dil. acetic acid, and if dried above 30° , insoluble. According to K. A. Hofmann and E. C. Marburg, 10 per cent. nitric acid, sulphuric acid, and acetic acid form a clear soln. of mercuric chloride and the ammonium salt. According to T. Weyl, a cold soln. of potassium hydroxide is without action, but H. Gaudechon says that in the cold an excess of the lye gives off three-fourths of the nitrogen, as ammonia; when the mixture is heated, ammonia is evolved; and L. Pesci, K. A. Hofmann and E. C. Marburg say that all the nitrogen may be driven off as ammonia by boiling the salt with potash-lye. L. Pesci also says that when distilled with sodium carbonate, three-fourths of the nitrogen is given off as ammonia; silver nitrate precipitates the chlorine completely; H. FÜRTH said that ethyl iodide in the absence of water forms primary ethylamine; and M. Zipkin, and E. Schmidt and L. Krauss said that methyl iodide—cold or hot, with or without methyl alcohol—gave tetramethyl-ammonium mercuric iodide: $\text{N}(\text{CH}_3)_4 \cdot \text{I} \cdot \text{HgI}_2$.

T. Weyl prepared white crystals of a compound with the empirical composition $\text{HgCl}_2 \cdot 2\text{NH}_3$ by dissolving mercuric chloride in liquid ammonia, and volatilizing the excess of ammonia. Unlike the preceding compound, however, T. Weyl's product gives off ammonia when treated in the cold with potash-lye, and it forms a yellow product—thought to be chloride of Millon's base, $\text{HO} \cdot \text{Hg} \cdot \text{NH} \cdot \text{Hg} \cdot \text{Cl}$. G. André reported an ill-defined hydrated form of mercuric diammino-chloride.

R. Varet obtained a precipitate of **mercuric triammino-chloride**, $\text{HgCl}_2 \cdot 3\text{NH}_3$, by the action of a soln. of dry ammonia in absolute alcohol upon dry mercuric chlorocyanide, HgCyCl . The compound is rapidly altered on exposure to air, and is decomposed by water. With aqua ammonia and mercuric chlorocyanide, infusible white precipitate, $\text{NH}_2 \cdot \text{Hg} \cdot \text{Cl}$, is formed; and with dry ammonia gas at 70° , a greyish-white complex, $4\text{HgCyCl} \cdot 3\text{NH}_3$, is formed. A. Naumann and J. B. Kämmerer passed dry ammonia into a half-sat. soln. of mercuric chloride in benzonitrile; and after the liquid was sat. with the gas, pressed the precipitate to free it from mother liquid. It was thought to be **mercuric tetrammino-chloride**, $\text{HgCl}_2 \cdot 4\text{NH}_3$. E. C. Franklin and C. A. Kraus prepared **mercuric dodecammino-chloride**, $\text{HgCl}_2 \cdot 12\text{NH}_3$, by dissolving mercuric chloride in liquid ammonia. The compound is stable only under press.; it solidifies at a low temp., and melts at -9° .

K. A. Hofmann and E. C. Marburg⁵ prepared **mercuric hydrazino-chloride**, $\text{HgCl}_2 \cdot \text{N}_2\text{H}_4$, by the action of hydrazine hydrate on an alcoholic or ethereal soln. of mercuric chloride. It is stable when dry. It decomposes with a hissing noise when heated, but it does not explode; it readily dissolves in mineral acids, and the soln. deposits some mercurous chloride. There is evidence of a decomposition analogous with the hydrolytic and aminolytic decomposition of mercuric amino-chloride in contact with water: $2\text{Hg}(\text{N}_2\text{H}_4)\text{Cl} = \text{N}_2\text{H}_4 + 2\text{HCl} + \text{Cl} \cdot \text{Hg} \cdot \text{NH} \cdot \text{NH} \cdot \text{Hg} \cdot \text{Cl}$. M. Adams has reported **mercuric dihydroxylamino-chloride**, $\text{HgCl}_2 \cdot 2\text{NH}_2\text{OH}$, or $\text{Hg}(\text{NH}_2\text{OH})_2\text{Cl}_2$, to be formed in needle-like crystals by mixing gradually at -10° cold alcoholic soln. of the component salts. The hydrazine and hydroxylamine in these compounds probably function in the same way as ammonia in the amino-compounds and as water of crystallization in hydrated salts.

§ 15. Double and Complex Salts of Mercuric Chloride—The Chloromercuriates

H. Rose¹ found that mercuric chloride is more readily soluble in hydrochloric acid than in water, and, as J. Davy showed in 1822, heat is developed during the reaction. The solubility of mercuric chloride in aq. soln. of hydrochloric acid has been measured by M. le Blanc and A. A. Noyes, by R. Engel, and by A. Ditte. According to R. Engel, at 0°, 100 c.c. of the soln. contain :

Grms. HCl	1.57	3.61	6.49	9.81	12.48	15.13	17.54	25.84
Grms. HgCl ₂	13.11	18.04	32.44	49.04	62.40	75.65	87.70	129.20
Sp. gr.	1.117	1.238	1.427	1.665	1.874	2.023	2.066	2.198

M. S. Sherrill calculated the ratio of the mol. conc. of hydrogen chloride to the increase in the solubility of mercuric chloride from A. Ditte's data at 16°, and found a rise from 1.0 to 3.3. This was attributed to the formation of complex ions, of the type HgCl₅". A. Ditte has reported hydrated forms of the HgCl₂ : HCl = 3 : 1; 2 : 1; 3 : 4; and 1 : 2 salts.

In 1822, J. Davy obtained a mass of needle-like crystals, which, according to P. F. G. Boullay's analysis, consist of **hydrotrichloromercuric acid**, HgCl₂.HCl, or HHgCl₃, by cooling a soln. with molecular proportions of the two components, HgCl₂ : HCl = 1.2, using an acid of sp. gr. 1.158. G. Neumann made the same salt by sat. a soln. of hydrochloric acid with mercuric chloride at the ordinary temp. of a room, and evaporating the liquid in a desiccator over sulphuric acid and quicklime at the temp. of a winter's cold, -0° to -4°. The heat of the reaction, according to R. Varet, is 0.86 Cal. J. Davy said that the crystals lose hydrogen chloride (and water) when heated, leaving mercuric chloride as a residue; they melt by the heat of the hand; and, according to G. Neumann, are decomposed by moisture. A. Ditte obtained white plates of **hydroheptachlorotrimercuric acid**, 3HgCl₂.HCl, or HHg₃Cl₇, by crystallizing a sat. soln. of mercuric chloride in hydrochloric acid

over 80° ; if the crystallization takes place at about 60° , needle-like crystals of $3\text{HgCl}_2 \cdot \text{HCl} \cdot 5\text{H}_2\text{O}$ are formed. P. F. G. Boullay (1827), and A. Ditte (1881) made prismatic crystals of **hydropentachlorodimercuric acid**, $2\text{HgCl}_2 \cdot \text{HCl} \cdot 4\frac{1}{2}\text{H}_2\text{O}$ and $2\text{HgCl}_2 \cdot \text{HCl} \cdot 6\text{H}_2\text{O}$ —the former from a soln. sat. at 30° , and allowed to stand at 20° ; the latter, by passing hydrogen chloride into a soln. in presence of an excess of mercuric chloride at 15° . The liquid, cooled by cold water, deposits, on standing, crystals which can be dried in an atm. of hydrogen chloride. M. le Blanc and A. A. Noyes say that **hydrotetrachloromercuric acid**, H_2HgCl_4 , must be formed in soln. because the f.p. of dil. hydrochloric acid is raised by additions of mercuric chloride and then again depressed with further additions of the salt. The electrical conductivity of hydrochloric acid also is decreased by the addition of mercuric chloride; sodium chloride behaves similarly, but potassium chloride does not since it forms a sparingly soluble double salt. G. Neumann obtained crystals of the salt $\text{HgCl}_2 \cdot 2\text{HCl}$ by cooling a soln. of the components in these proportions to -12° . R. Varet gives 0.80 Cal. for the heat of formation. A. Ditte obtained crystals of **hydrotetrachloromercuric acid**, $\text{HgCl}_2 \cdot 2\text{HCl} \cdot 7\text{H}_2\text{O}$, by saturating a hydrochloric acid soln. of mercuric chloride at -15° , and at -10° passing a current of hydrogen chloride. The crystals are dried on a porous tile at -5° . By working at 5° instead of -10° , A. Ditte claimed to have made crystals of **hydrodecachlorotrimercuric acid**, $3\text{HgCl}_2 \cdot 4\text{HCl} \cdot 14\text{H}_2\text{O}$. It is not yet clear which of these substances is a mixture and which a true compound. C. R. Crymble says that when hydrochloric acid is added to a $\frac{1}{10}\text{N}$ -alcoholic soln. of mercuric chloride, the absorption increases up to a maximum with equimolar proportions of HCl and HgCl_2 , and he says that the presence of higher complexes than $\text{HgCl}_2 \cdot \text{HCl}$ cannot be proved in soln.

Y. Shibata, T. Inouye, and Y. Nakatsuka observed that soln. of complex salts extend their absorption bands towards the ultra-violet zone more than do the component salts. With this criterion, they inferred that mercuric chloride forms complex salts with the chlorides of hydrogen, ammonium, sodium, potassium, magnesium, zinc, cadmium, calcium, strontium, barium, manganese, cobalt, nickel, aluminium, zirconium, and tin; with the bromides of ammonium, sodium, potassium, zinc, and cobalt; and with the iodides of cadmium.

Mercuric chloride is readily soluble in water containing ammonium chloride in soln. At 15.6°J . Davy found 100 parts of a sat. soln. of ammonium chloride dissolve almost an equal weight (99.56) of mercuric chloride. About the time of Paracelsus, a compound of sal ammoniac with corrosive sublimate was prepared by crystallization from a soln. of mercuric chloride with an excess of ammonium chloride, and employed medicinally by the iatrochemists under the name *sal sapientiæ*—the *salt of wisdom*—or *sal alembroth*—*ἄμβροτος*, immortal, gold-like, divine. G. C. Wittstein² made it by boiling a soln. of ammonium chloride with mercuric or mercurous oxide or carbonate—with the mercurous compounds some metal separates out. The heat developed on mixing soln. of ammonium and mercuric chlorides has been studied by R. Varet— $(\text{HgCl}_{2\text{aq.}} \cdot \text{NH}_4\text{Cl}_{\text{aq.}}) = 0.54 \text{ Cal.}$, $(\text{HgCl}_{2\text{aq.}} \cdot 2\text{NH}_4\text{Cl}_{\text{aq.}}) = 0.98 \text{ Cal.}$ —the lowering of the f.p., by F. M. Raoult, and by H. C. Jones and N. Knight; and the electrical conductivity, by H. C. Jones and K. Ota. According to R. Schindler and F. L. Winckler, the soln. containing a mixture of equal parts of mercuric and ammonium chlorides gives a white precipitate with the alkali carbonates or hydroxides; with water containing calcium carbonate in soln.; and sugar precipitates calomel from hot soln. (87°), but not from cold soln. Alembroth salt is probably a mixture of ammonium chloride with $\text{HgCl}_2 \cdot 2\text{NH}_4\text{Cl} \cdot \text{H}_2\text{O}$. J. D. Holmes reported the salts $(\text{NH}_4)_2\text{Hg}_9\text{Cl}_{20}$ and $(\text{NH}_4)_2\text{Hg}_3\text{Cl}_8 \cdot 4\text{H}_2\text{O}$, but gave no satisfactory evidence in support of their chemical individuality.

As E. Soubeiran³ showed in 1827, when a soln. containing equal parts of ammonium and mercuric chlorides is evaporated and cooled, a crop of crystals of ammonium chloride first separates in cubic crystals, often twinned; these are followed by the rhombic pyramids or needle-like crystals of the compound **monohydrated ammonium tetrachloromercuriate**, $\text{HgCl}_2 \cdot 2\text{NH}_4\text{Cl} \cdot \text{H}_2\text{O}$, or $(\text{NH}_4)_2\text{HgCl}_4 \cdot \text{H}_2\text{O}$.

E. Soubeiran said that the crystals of the latter salt were to be mechanically picked out from those of the ammonium chloride, and purified by recrystallization. P. A. Meerburg's work at 30° shows that these crystals are alone obtained from soln. with between 21.4 and 24.3 per cent. of ammonium chloride and 50.6 and 56.0 per cent. of mercuric chloride with respectively 24.79 and 50.05 per cent. of ammonium and mercuric chloride, a mixture of ammonium chloride and $\text{HgCl}_2 \cdot 2\text{NH}_4\text{Cl} \cdot \text{H}_2\text{O}$ is formed at 30°; and with respectively 20.06 and 58.97 per cent. of ammonium and mercuric chloride, a mixture of $\text{HgCl}_2 \cdot 2\text{NH}_4\text{Cl} \cdot \text{H}_2\text{O}$ and $\text{HgCl}_2 \cdot \text{NH}_4\text{Cl} \cdot \text{H}_2\text{O}$ separates out at 30°. According to A. Johnsen, the rhombic crystals have the axial ratios $a:b:c=0.7120:1:0.7725$, and sp. gr. 2.84; J. Grailich says they have a strong positive double refraction. C. F. Rammelsberg said the crystals are isomorphous with those of potassium tetrachloromercuriate, $\text{K}_2\text{HgCl}_4 \cdot \text{H}_2\text{O}$. H. Töpsöe made an analogous series of substituted ammonium compounds: *e.g.*

$[\text{NH}_3(\text{CH}_3)]_2\text{HgCl}_4$	•	monoclinic	$a:b:c=0.6030:1:0.8488$, $\beta 96^\circ 20'$
$[\text{NH}_3(\text{C}_2\text{H}_5)]_2\text{HgCl}_4$	•	tetragonal	$a:c=1:0.9243$
$[\text{NH}_2(\text{C}_2\text{H}_5)_2]_2\text{HgCl}_4$	•	monoclinic	$a:b:c=0.6515:1:0.4555$, $\beta 94^\circ 56'$
$[\text{NH}(\text{CH}_3)_3]_2\text{HgCl}_4$	•	monoclinic	$a:b:c=0.7033:1:0.4698$, $\beta 92^\circ 3'$
$[\text{NH}(\text{C}_2\text{H}_5)_3]_2\text{HgCl}_4$	•	hexagonal	$a:c=1:0.8451$
$[\text{N}(\text{CH}_3)_4]_2\text{HgCl}_4$	•	rhombic	$a:b:c=0.3766:1:0.7893$
$[\text{N}(\text{CH}_3)_3(\text{C}_2\text{H}_5)]_2\text{HgCl}_4$	•	rhombic	$a:b:c=0.7263:1:0.8458$
$[\text{N}(\text{CH}_3)_2(\text{C}_2\text{H}_5)_2]_2\text{HgCl}_4$	•	rhombic	$a:b:c=0.7660:1:0.8660$
$[\text{N}(\text{CH}_3)(\text{C}_2\text{H}_5)_3]_2\text{HgCl}_4$	•	tetragonal	$a:c=1:0.737$
$[\text{N}(\text{C}_2\text{H}_5)_4]_2\text{HgCl}_4$	•	tetragonal	$a:c=1:1.2190$

According to E. Soubeiran, the crystals of hydrated ammonium tetrachloromercuriate are stable in air; they become opaque at 40°; and lose 5.5 per cent. of water. They decompose when heated and a mixture containing ammonium and mercuric chlorides is obtained as a sublimate. The crystals are almost perfectly miscible with boiling water, but at 10°, the solubility is 40 per cent. When a little hydrogen sulphide is passed into the soln. a white precipitate is formed; with more of the gas, the precipitate blackens; sodium or potassium hydroxide gives a white precipitate and ammonia gas is evolved; aqua ammonia, says C. H. Hirzel, gives a white precipitate, but E. Soubeiran said that no precipitate is formed; the latter added that sulphuric, hydrochloric, or nitric acid produces no visible change. According to C. H. Hirzel, crystals containing a lower ratio than $\text{HgCl}_2:\text{NH}_4\text{Cl}=1:2$ cannot be obtained. J. M. Thomson and W. P. Bloxam reported the separation of crystals of the trihydrated salt, $\text{HgCl}_2 \cdot 2\text{NH}_4\text{Cl} \cdot 3\text{H}_2\text{O}$, by seeding a supersaturated soln. with prismatic crystals of mercuric chloride precipitated from hot soln., but P. A. Meerburg did not find these crystals.

FIG. 15.—P. A. Meerburg's Equilibrium Diagram for the Ternary System, $\text{HgCl}_2-\text{NH}_4\text{Cl}-\text{H}_2\text{O}$.

At least nine salts have been reported—taking the order $\text{HgCl}_2-\text{NH}_4\text{Cl}-\text{H}_2\text{O}$; these are 5.1.0; *9.2.0; 2.1.0; 3.2.0; *3.2.1; *1.1.0; *1.1.1; *1.2.1; and 1.2.3. The five marked with an asterisk were alone found by P. A. Meerburg to be stable in aq. soln. at 30°. P. A. Meerburg applied the principles of the phase rule to the ternary system, $\text{HgCl}_2-\text{NH}_4\text{Cl}-\text{H}_2\text{O}$, at 30°, and the results are summarized in the diagram, Fig. 15, which shows the composition of the soln. The points X, Y, Z respectively denote the components HgCl_2 , NH_4Cl , and H_2O ; P represents the solid phase $\text{HgCl}_2 \cdot 2\text{NH}_4\text{Cl} \cdot \text{H}_2\text{O}$; Q, $\text{HgCl}_2 \cdot \text{NH}_4\text{Cl} \cdot \text{H}_2\text{O}$; R, $3\text{HgCl}_2 \cdot 2\text{NH}_4\text{Cl} \cdot \text{H}_2\text{O}$; and S, $9\text{HgCl}_2 \cdot 2\text{NH}_4\text{Cl}$. The isothermal line ABCDEFG has six branches showing the composition of the soln. in stable

equilibrium with the solid phases— AB with HgCl_2 ; BC , with 9.2.0; CD , with 3.2.1; DE , with 1:1:1; EF , with 1.2.1; and FG , with NH_4Cl . The line AB may extend to B_1 indicating that the solid phase, HgCl_2 , is then in a metastable condition, and passes more or less quickly into the 9.2.0 phase. This solid phase is voluminous and cryptocrystalline. The line AB represents the composition of soln. in equilibrium with the solid phase $9\text{HgCl}_2 \cdot 2\text{NH}_4\text{Cl}$; CD , with $3\text{HgCl}_2 \cdot 2\text{NH}_4\text{Cl} \cdot \text{H}_2\text{O}$; DE , with $\text{HgCl}_2 \cdot \text{NH}_4\text{Cl} \cdot \text{H}_2\text{O}$; EF , with $\text{HgCl}_2 \cdot 2\text{NH}_4\text{Cl} \cdot \text{H}_2\text{O}$; and FG , with NH_4Cl . Soln. represented by points inside the sectors deposit the solid phase represented by the corresponding equilibrium line. Soln. represented by points on B , C , D , E , and F , are in equilibrium with two solid phases. The point G represents the solubility of ammonium chloride in water; A that of mercuric chloride.

J. Davy prepared crystals of what he regarded as a double salt, $\text{HgCl}_2 \cdot \text{NH}_4\text{Cl}$ —that is, **ammonium trichloromercuriate**, NH_4HgCl_3 —by sublimation from a mixture of equimolar parts of the two components; D. Strömhold says this compound is the end-product of the extraction of the higher mercuric ammonium chlorides, say, $9\text{HgCl}_2 \cdot 2\text{NH}_4\text{Cl}$; and H. Edhem-Bey made it by treating mercuric amido-chloride, NH_2HgCl , with chloroform and allowing the mixture to stand in light or shaking every now and again during 5 weeks. The soln. is then evaporated. R. J. Kane says he obtained the salt by crystallization from an aq. soln. of its components, but P. A. Meerburg failed to find any evidence of the existence of this salt in aq. soln. at 30° , so that R. J. Kane's product was probably **monohydrated ammonium trichloromercuriate**, $\text{NH}_4\text{HgCl}_3 \cdot \text{H}_2\text{O}$, since P. A. Meerburg has shown that at 30° this hydrated product separates from aq. soln. with between 18.86 and 56.83 per cent. respectively of ammonium and mercuric chlorides, and 14.22 and 56.71 per cent. of the same two chlorides; with soln. containing 19.98 and 58.89 per cent. respectively of ammonium and mercuric chlorides, a mixture of the 2.1.1 and 1.1.1 salts is formed; and with 14.10 and 57.04 per cent. respectively of the same two salts, a mixture of the 1.1.1 and 3.2.1 salts is formed. R. J. Kane also made the monohydrated salt, and E. Mitscherlich said that it is isomorphous with the corresponding potassium salt. J. Davy says the anhydrous salt melts readily, and forms a greyish-white crystalline mass on cooling. C. Tourneux also made the monohydrate.
